A 15 per cent. alcoholic solution of anisol rubbed on such parts as might be first invaded—for example, the neck—is said to have a deterrent action. In conditions of travel approximating to service conditions, however, where frequent changes of underclothing are impossible or heavy infestation is to be feared, the N.C.I. powder (naphthalene, with creosote 2 per cent. and iodoform 2 per cent.) should be dusted at two-day intervals into the underclothing, except at the fork and the armpits, where it may cause severe irritation. For these situations, and as a general adjuvant to N.C.I., "vermigel" may be used. Those with sensitive skins may find difficulty in tolerating any of these remedies. The habits, the frequent changes of underclothing, and the vigilant eye of the ordinary clean Englishman will, however, in peace-time conditions, even in the Near East, greatly assist to preserve him from the low-grade infectivity of typhus without additional precautions. If actually engaged in medical or relief work in typhus areas, however, stringent precautions should be taken, especially with regard to louse-proof clothing.

TRANSMISSION OF PLAGUE BY RATS.

PROFESSOR J. J. VAN LOGHEM, director of the Department of Tropical Hygiene at the Colonial Institute, Amsterdam, delivered one of the series of Chadwick Public Lectures in London on March 2nd, when he dealt with the plague question as it affected Europe past and present. He confined himself to bubonic plague, which he regarded as being the plague of all the great historical epidemics, and his argument was that in the time of old Europe the domestic architecture, the habits of the people, and the sanitary conditions generally were such as to encourage the breeding of rats in much closer proximity to man than was the case anywhere in Western Europe to-day. At the time of the plague outbreaks in London and Amsterdam in the seventeenth century the rat probably lived as near to the occupants of dwelling-houses as it did at the present time in the plague-stricken areas of the tropics and subtropics. In this connexion he spoke of his recent investigations in Java, where he found the house rat—*Mus rattus*—making its nest inside the bamboo poles used for the beams of the houses and the supports of the beds. Plague infection, in his view, depended upon the distance between rat and man being sufficiently short to permit of the rat-flea conveying the disease to man. The influence of climate and season upon the rat-flea carrying the plague parasite accounted for the climatic and seasonal variations of rat-borne plague. He showed diagrams illustrating the fluctuations of the plague in London and in certain Dutch towns in the seventeenth century. In all these cases the highest point was reached in August and September, after which there was a sharp decline. He quoted Daniel Defoe's *Journal* to prove that in the winter and spring preceding the plague of 1665 in London isolated cases appeared within a few weeks of each other and traceable to the same neighbourhood—Long Acre—although it was not until the summer that any epidemic arose. There was no difficulty in explaining these sporadic cases in the light of modern knowledge if it was remembered that the propagation of the plague depended not on contact between human beings but on the activity of the rat-flea, for the supposition was that all through this epidemic-free period there was plague among the rats, and only when the seasonal conditions favoured insect activity did the epidemic arise among human beings. His pupil, Dr. Dykstra of Amsterdam, had made some interesting researches on the plague which occurred in that city in 1617, by studying the lists of the Carthusian burial ground. They gave full particulars of the persons interred, including their places of residence, and he found that for six weeks in the early summer the plague was strictly localized to two or three streets; later it spread over a large quarter of the town, but its spread was topographical, from house to house and street to street. There was no other explanation of such a picture than localized rat plague. The animal concerned was not the brown or grey rat now familiar, but the black house rat, the "big

¹ *Annales de l'Institut Pasteur*, 1916.
² *Lancet*, August 20th, 1921.

mouse," which was rarely seen in Europe to-day. Even in the time of Cuvier the black rat, though still common, was being ousted by the brown, but it was a rat of the same species as this former domesticated inhabitant of Europe which caused the recent outbreak of plague in Java. That the brown rat can carry plague in the same way is, of course, evident; it was the brown rat which was responsible for the small epidemic in Paris in 1920, when most of the 150 victims were rag dealers, who were compelled by their trade to live near to the haunts of the rats; but the point is that the brown rat is not a domesticated animal like its predecessor, and to that extent is less dangerous. In the old days, with dark house interiors, straw beds, and abundance of food and other stores kept in dwellings, the black rat had a fertile breeding-ground. Professor Van Loghem paid a high tribute to British work on plague. He said that before the plague appeared in the Dutch Indies the hygienists of Holland were well acquainted with the investigations of British epidemiologists—he mentioned a dozen names—and when in 1911 the plague came to Java, fifteen years after it had come to Bombay, they had only to avail themselves of the ideas with which British research had furnished them.

THE NATURE OF THE VIRUS OF VACCINIA.

A METHOD which permits of the isolation and concentration in suspension of the infective agent of vaccinia has been devised by MacCallum and Oppenheimer.¹ Briefly stated, it is a method of differential centrifugalization with the use of suspending fluids of different specific gravities, and it is applicable to the purification of vaccine lymph from bacterial and other contamination. The same procedure may be applied to the study of many diseases, the infective agent of which is unknown or difficult of isolation, such as small-pox, measles, scarlet fever, typhus fever, rabies, and all the various infections supposed to be due to ultramicroscopic organisms. A commercial sample of calf lymph, the specific gravity of which was determined as 1.1638, was centrifugalized at high speed for an hour in small narrow tubes of 1 c.cm. capacity. The lymph separated into a solid mass of sediment, a thick turbid layer, and a superficial less turbid layer. The separate layers were inoculated on the rabbit's cornea, and only the superficial layer produced the typical vaccine lesion. This layer was pipetted off, mixed with Locke's solution (the specific gravity of the mixture being 0.99), centrifugalized, and the upper and lower layers tested on the rabbit's cornea as before. It was now found that the virus had sunk to the bottom of the tube, showing that the specific gravity of the infective agent was higher than the last figure. A series of flasks was prepared with mixtures of glycerin and Locke's solution varying in specific gravity from 1 to 1.6, and with these suspending fluids the specific gravity of the virus itself was approached from both sides. Each mixture was accurately weighed and the specific gravity of the final mixture thus ascertained. By inoculating top layer and bottom layer in each case it was found that the virus floated in a suspending fluid of specific gravity 1.14 and sunk when the specific gravity was 1.11. Its own specific gravity is probably about 1.12 or 1.13. To purify it, therefore, it seemed best to wash it and centrifugalize it in a suspending fluid just heavier than itself, for by so doing the maximal removal of contaminating material will be removed. When this was done, the examination of a drop of the virulent top layer under the microscope with dark ground illumination showed myriads of minute granules of uniform size, very much smaller than streptococci or staphylococci. They shone dully and exhibited Brownian movement. The granules occurred singly, in small groups, or in tiny beaded chains which were about one-tenth the size of a chain of streptococci with the same number of elements. They stained faintly with methylene blue, were Gram-negative, and took a deep colour with carbol-fuchsin. The granules are apparently identical with those seen in tissues

and smeared from vaccinia and small-pox by Prowazek and others. So far the authors have not succeeded in agglutinating them with the immune serums at present available.

EFFECTS OF GAMMA RAYS FROM A LARGE QUANTITY OF RADIUM.

THE promised report of the Medical Research Council on the effects of the gamma rays from a large quantity of radium has been published.¹ The radium employed amounted to nearly 5 grams of hydrated radium bromide, or about 2½ grams of radium element, which was collected by the Ministry of Munitions from innumerable gun-sights, watch-dials, and other instruments of war, and handed over for the purpose of medical research. The whole quantity of radium salt thus made available was, in the first instance, put in the charge of the late Mr. Cecil Lyster—whose untimely death in January, 1920, was a great loss to medicine, and especially to his chosen field of radiology—Professor W. S. Lazarus-Barlow, and Professor Sidney Russ. The object of the first inquiries was to determine the curative value in malignant disease of penetrating radiation of extremely short wavelength, like that of the gamma rays of radium, in order to ascertain whether the use of this very large amount of radium would give appreciably different results, in kind or degree, than had been obtained hitherto with quantities of about a tenth of the amount. This work was done in the cancer wards and research laboratories of the Middlesex Hospital, with the clinical collaboration of the physicians and surgeons of the hospital. Special apparatus was designed by Dr. S. Russ for the custody and employment of the unusually large quantity of radium and for the protection of the workers. When the radium salt was not actually in use for the treatment of patients it was employed for experimental exposures of various animals. In 1920 the Treasury gave its sanction to the formal transference of the radium, at its insurance value of £72,500, from the Disposal Board of the Ministry of Munitions to the Medical Research Council, in order to maintain its use for research purposes, and at the conclusion of the preliminary period of mass experiment at the Middlesex Hospital the Council arranged for the distribution of the radium among several research centres in London, the provinces, Wales, Scotland, and Ireland. At each centre special attention is being concentrated upon particular forms of malignant disease and their treatment. The report is divided into six chapters. The first chapter, by Dr. W. S. Lazarus-Barlow, Dr. S. Russ, and Dr. Helen Chambers, deals with the use of the gamma rays from a large quantity of radium in the treatment of malignant disease; the conclusion is that the majority of malignant growths exhibit a high degree of resistance to the radiation; some few types of growth (lymphosarcomata, for example) have seemed more susceptible, but others (squamous epitheliomata, for instance) have proved more refractory. The amount of pain due to the damage of the skin has been very variable, and the degree of injury to the skin seems to be definitely influenced by the local vascular supply. Sometimes the effect of radiation has been to hasten ulceration, and an additional factor influencing this result is the effect of the radiation on sepsis, for there seems little doubt that if a growth is already infected the radiation produces favourable conditions for the growth of bacterin. One of the chief features of interest in the application of this large quantity of radium was the general physiological reaction of the patients; under the conditions adopted the whole body received an appreciable amount of gamma radiation, and during exposures lasting four or five hours several patients complained of headache and sickness, followed by a feeling of general malaise lasting a few days. Another observation of importance was that occasionally marked oedema would supervene within twenty-four hours of the radium exposure. The investigators are convinced that it is necessary for the physician, surgeon, radiologist, and pathologist to work

¹ Journ. Amer. Med. Assoc., February 11th, 1922.

together in the treatment of malignant disease. The second chapter, by Dr. W. S. Lazarus-Barlow, deals with the histological changes produced in certain neoplastic and normal tissues in man by the gamma rays of radium. The result of the exposure to a considerable degree of radiation is apparently that there is a disappearance of cytoplasm from the neoplastic cells, more marked after a single than after two exposures; the intranuclear relations are altered; there is increased tendency to the occurrence of localized degeneration of neoplastic cell masses; the connective tissue fibres permeating the growth become collagenous; the appearance of lymphocytic or small mononuclear cells—usually found in advance of the growing edge of a malignant neoplasm—is less extensive than usual; and there is no evidence of proliferative change in connective tissue or endothelium. The third chapter of the report, also by Dr. Lazarus-Barlow, deals with the histological and some other changes produced in animals by exposure to the gamma rays of radium; it is founded on the examination of a large number of frogs, rats, rabbits, and cats, exposed under different conditions to the gamma radiation of the mass of radium bromide. The fourth chapter is a separate report by Dr. T. Morowoka and Sir Frederick Mott upon the appearances found in the brains of the animals; and the fifth chapter, by Dr. C. Price Jones, deals with the changes produced in the bone marrow in rabbits. Chapter six is a short report on the average range of beta rays in different metals, by Mr. G. A. Sutherland and Mr. L. H. Clark.

HOOKWORM IN CORNWALL.

In a recent article in our column on the work of the Medical Research Council (January 23rd, 1922, p. 152) mention was made of investigations into ankylostomiasis, particularly as found among the workers in Cornish tin mines. Twenty years ago Haldane and Boycott found that a large proportion of the underground workers in certain of these mines were infected by hookworm. Since that time two simple measures have been brought into operation at the mines, one of them the lowering of the temperature by means of improved ventilation, and the other the bucket transport of faecal matter to the surface from below. Professor R. T. Leiper, at a meeting of the Section of Tropical Medicine of the Royal Society of Medicine on March 6th, brought forward some recent investigations which showed, so far as they went, that hookworm infection, thanks to these measures, had very greatly diminished. His investigation, in which Dr. M. Khalil and Mrs. Philpot were associated, was undertaken during a period of three weeks in the summer of 1920, at a time when the industrial depression now so severe in Cornwall was just beginning, so that the facilities available were not of the best. The number of workers examined was 130, and of these only eight (or 6.1 per cent.) were found to harbour the parasite, as compared with something like 80 per cent. in part of the earlier investigations. In the Dolcoath mine—which had a very bad pre-eminence at the time of the inquiry by Haldane and Boycott—out of 34 underground workers examined, only two were found to be infected; in the neighbouring mines not a single case was discovered, but at a newly worked mine at East Pool, where there had been a breakdown of the pumping machinery, so that the sanitary precautions at the time of the investigation were not fully effective, out of 22 people examined the ankylostoma was found in 6. Other parasitic worms were found with considerable frequency, showing that there was gross faecal contamination, but Professor Leiper believed that the chief factor in accounting for the diminution in the hookworm infection was the lowering of the temperature of the mine, which resulted in the death of the parasite in the larval stage. He also showed a propaganda film on hookworm disease, prepared by the International Health Board of the Rockefeller Foundation. It was a very lively and popular piece of cinematography, with startling captions, intended to drive home the need for personal and domestic hygiene. One

remarkable portion of the film showed the intestine of a dog recently dissected with the ankylostomes still alive and active.

THE GOVERNMENT AND THE GEDDES REPORT.

The Geddes Committee's report on public economics extends into three Blue Books, of which summaries have appeared in the SUPPLEMENT; it covers practically all the departmental services. No one could expect Sir Robert Horne, in stating what the Government intends to do on the recommendations, to make his analysis and exposition follow strictly parallel lines. That was impossible in a speech of two hours and a half. The matter was rendered the more difficult because the Geddes Committee had reached their totals for reductions by including sums for cuts the nature of which they did not specify but only indicated. Further, it is obvious that in dealing with men and contracts varying time would be required for effecting economies. But the conclusions can be put succinctly. The Geddes Committee suggested cuts to the amount of £86,000,000, of which £71,000,000 was specified. The Government propose cuts on the same basis to the amount of £53,000,000, or, including what can be done as the result of the Washington Conference, £64,000,000. Of this sum £54,000,000 will be realizable in the financial year 1922-23, and will be in addition to reductions amounting to £75,000,000 previously made by the departments themselves. By far the largest savings will, as expected, be in the fighting services, and these will be obtained by the reduction in the numbers of officers and men. Another comparison by Sir Robert Horne was still more striking as an indication of what is being done. Taking into account the supplementary estimates of the present year, which have so weighted the expenditure, he said that the estimates for next year offered a total reduction of £181,000,000. But that, of course, is subject to any supplementary estimates in the later period. The Government is frankly proceeding not only on lines of economy but on a decision that the country must do without various things which would be afforded in normal times. On the other hand, they are bound to remember, in regard to the health services, for example, that a cutting of expenditure may mean an actual loss to the nation in other ways; and for that reason the Geddes Committee itself showed restraint in its counsel in this connexion. The reduction proposed by the committee was £2,100,000; and that was accepted by the Ministry, though it is to be secured in somewhat different ways, and with some sacrifices that must be regretted. The war pensions did not come under review, as they were fixed some time ago, subject to small modifications periodically, as the decline in the cost of living may permit. It would be a mistake to assume that the Government has decided, in regard to grants through departments as a whole, that the percentage system is to be abandoned. The balance of opinion (adds our parliamentary correspondent) is against it, as it does not give adequate control, and rather encourages expenditure by local authorities, but there are objections to the block grant system in that it may also tend to perpetuate an allowance to be lived up to by the local authorities. The proposal to raise the age of entry in elementary schools to 6 years has been rejected.

TERRITORIAL ARMY REDUCTIONS.

The Secretary of State for War recently called together the Presidents and Chairmen of County Associations in order to announce to them the reductions in Territorial Army expenditure decided upon by the Army Council in consequence of the pressing demand for economy of public money. Part of this reduction, we understand, will consist in the disbandment of units and the consequent removal from the Active List of officers and other ranks who thus become supernumerary to establishment; there will also be a proportionate reduction in buildings. According to this plan of economy the number of Territorial general hospitals will be reduced from 23 to 3, and the number of casualty clearing

stations from 15 to 8. So far as the general hospitals are concerned, it is probable that all the existing units will be disbanded with the exception of the three to be retained. Further, each Territorial division will have only one field ambulance instead of three as at present; this is to be effected in the main by amalgamating the three existing divisional field ambulances to form a single unit. It is proposed to cut down the establishment of officers in the surviving medical units: Territorial general hospitals are to have 10 instead of 32 officers, clearing stations 6 instead of 12, field ambulances 6 instead of 8, and cavalry field ambulances 6 instead of 7. The establishments of "other ranks" will not be reduced in field ambulances, but slight reductions are proposed in the personnel of Territorial clearing stations and general hospitals. It may confidently be assumed that the wholesale disbandment of general hospitals goes far beyond any reduction in which the medical advisers would be willing to concur on grounds of safety and efficiency, and serious representations should be made when parliamentary sanction is sought for these economies. According to our information there is another proposal affecting the Territorial medical service which needs publicity. The reduction is small, but it appears to inflict a distinct hardship upon a number of Territorial medical officers. At the present time each Territorial Division has in peace time a headquarters medical staff of three officers: an assistant director of medical services, who is a Territorial officer and unpaid; a deputy assistant director of medical services, also a Territorial officer, but receiving pay for full-time services; and an adjutant, who is a Regular officer (with full pay and pension rights) and is attached to the Divisional school of instruction. It is proposed that the fourteen D.A.D.M.S. appointments shall be abolished and the holders thereof given two months' notice, the adjutants of the regular R.A.M.C. being retained. Since the appointment of D.A.D.M.S. was understood to be for four years, the Territorial officers holding them incurred domestic commitments, and we are strongly of the opinion that (assuming the economy to be necessary in the public interest) the notice given these officers is far too abrupt. We therefore hope that the medical members of Parliament will watch this matter when the Secretary of State for War makes his statement in the House of Commons. The Army Council has evidently made up its mind, but the final decision rests with Parliament.

A course of advanced lectures in medicine by professors in the Faculty of Medicine of Paris has been arranged by the University of London, and will be given at the house of the Royal Society of Medicine, 1, Wimpole Street. The first, on March 20th, by Professor H. Roger, will be on the functions of the lung; at this lecture the Vice-Chancellor of the University, Sir S. Russell-Wells, will preside. The second, on March 23rd, by Professor A. Chauffard, will be on the humoral syndrome of gout; Sir Thomas Lewis, F.R.S., will be in the chair. The third, on March 27th, by Professor P. Duvall, will deal with the present position of intrathoracic surgery; Mr. W. Sampson Handley will preside. The lectures will be given at 5 p.m. on the days mentioned. The course will be continued by other lecturers in May.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

Geddes Committee Report.

The Government's Intentions.

THE Chancellor of the Exchequer, Sir Robert Horne, on March 1st reviewed in detail the recommendations of the Geddes Committee for the reduction of national expenditure, and announced the intentions of the Government. He said that when the Committee were asked to make suggestions for cutting down the Estimates by a hundred millions it was not expected that they would be able to do so much, but they were given a round figure to aim at. The cuts which they advised amounted to eighty-six millions sterling, and these he had to consider.

In regard to education, Sir Robert Horne said, the Committee recommended a reduction of eighteen millions, but part of that (about three millions) would be simply a transfer of burden from the taxpayer to the ratepayer. The two principal submissions were for a lowering of teachers' salaries and the exclusion from school of children under 6. The Government had decided that neither of these proposals could be put into operation. There was no doubt that the health of the children of this country had been immensely improved by the medical attention and the care which they had at school during these tender years; and it would be a grave injury to many of the homes in this country if, when women were battling with the difficulties of life in trying to support their families, they were forced to keep their children away from school, where at present they received the only mothering they could get. The Government, however, did see its way to save six and a half millions on the education votes. They accepted the proposal of the Geddes Committee that teachers should contribute 5 per cent. of their salaries towards their pensions, and this arrangement would yield nearly two million pounds. They were also in favour of increasing the size of the classes as far as practicable.

The Committee also recommended a reduction of twenty-one million in the Army, and a reduction of what might be called "other ranks" of thirteen millions were in respect of specified items. The other seven millions were a kind of margin which might readily be represented by savings effected at Washington. Anyway, on definite figures there was a difference of only four millions between the Committee and the Admiralty, and this resolved itself almost entirely into the number of the personnel of the Navy. The number of men in the Navy now was 122,700; the Admiralty proposed to reduce it to 121,600; the Geddes Committee proposed 88,000. The Admiralty had since agreed to 98,000 men, and the Government held that this figure should be accepted. It would be quite impossible, however, to bring about this saving by March 31st of this year; on the other hand, he hoped that in the course of next year, still greater reductions in naval expenditure might be obtained.

As regards the Army, the Geddes Report advised a reduction of twenty millions, or £22,500,000 including the Middle East, but again there was a vague sum of £7,000,000 for unspecified reductions, therefore the reduction recommended was £15,500,000. Against that the War Office suggested a reduction of £17,000,000. The difference was on the question of numbers. The Committee advised a reduction of 54,000 men; the War Office accepted one of 33,000. Afterwards it was discovered that the 54,000 recommended by the Geddes Committee was based on a misapprehension, really due to a change of mind on the part of the Indian Government as to its necessities. The revised figure of the Geddes Committee therefore was 39,000, and the War Office proposal was 33,000; the Government could not recommend any further curtailment. For the Air Force the cut recommended was five and a half millions, including one million unspecified. The Air Minister proposed a reduction of three millions. The Government gave these recommendations to the House as those which could be most justified in existing conditions. The suggestion by the Geddes Committee that there should be set up a Ministry of Defence would be referred for consideration to the Committee of Imperial Defence.

Coming next to the portion of the report which dealt with the Ministry of Labour and the recommendation for amalgamation of Health Insurance and Unemployment Insurance, Sir Robert Horne said that preparations were being made for a complete investigation into the possibility of carrying out some such scheme. For the Ministry of Health the reduction proposed was £2,100,000, and that had been accepted. As to War Pensions, he was able to say that the administration had themselves put forward suggestions for a reduction of six millions, and these had been adopted both by the Geddes Committee and the Government. The saving was entirely effected by economies in the working of the department itself.

After referring to various other departments Sir Robert Horne, in summing up, said that for the purpose of comparison he deducted from the eighty-six millions aggregate recommendations the sum of fifteen millions for unspecified possible savings, and so reached a figure of £71,000,000. The Government accepted in all a reduction of £64,000,000, but that would include £10,000,000 attributable to possible savings as the result of the Washington Conference, and £1,000,000 saving on the supply of oil. This brought him down to £53,000,000, and the difference between the figures of £71,000,000 and £53,000,000 was £18,000,000. Of that, £12,000,000 were represented by the education reduction proposals of the Geddes Committee, which the Government could not accept, and beyond that there was only £6,000,000 between the Committee and the Government. Sir Robert Horne went on to say that with the savings already effected he hoped that the estimates for next year would be £181,000,000 less than the estimates for the present year, and in reply to Mr. Asquith as to how he got these figures he explained that for purposes of comparison he was including the supplementary estimates.

In the course of debate Mr. J. H. Thomas, for the Labour party, declared uncompromising opposition to any proposal to amalgamate health and unemployment insurance. Lieut.-Colonel Sir Arthur Warren advised caution in the consideration of such amalgamation.

Voluntary Hospitals Grant.

Mr. Gilbert asked, on March 1st, if the Hospitals Commission had now distributed the £500,000 voted to assist the voluntary hospitals, and whether there was an improvement in the position of the London institutions. Sir A. Mond replied that the Voluntary Hospitals Commission anticipated

that the grants made during the present financial year would amount approximately to £120,000, of which £87,900 had been paid to London hospitals. Applications for grants to the local Voluntary Hospitals Committee were dealt with as soon as they were received. Hospitals had been asked to expedite their application, but comparatively few had as yet been received, as their accounts for the year were not made up. Although the figures were not complete, the King's Fund estimated that the aggregate deficit for the London hospitals would be substantially less than in 1920, and it was probable that the same would be the case for the provincial hospitals. The Minister gave the following list of grants for London approved by the Voluntary Hospitals Commission up to February 28th, 1922:

	£
Canning Town	700
East London Hospital for Children	3,000
Elizabeth Garrett Anderson Hospital for Women	600
Royal Northern Hospital	11,000
Hospital for Epilepsy	850
Hospital for Sick Children	4,000
Infants' Hospital	1,000
King's College Hospital	9,000
London Hospital	10,000
London Temperance Hospital	2,000
Metropolitan Hospital	750
Middlesex Hospital	3,000
Mildmay Mission Hospital	400
National Hospital for the Paralysed	800
Prince of Wales's General Hospital	2,200
Queen Charlotte's Lying-in Hospital	3,000
Queen Mary's Hospital for the East End	1,000
Queen's Hospital for Children	2,100
Royal Free Hospital	12,000
Royal National Orthopaedic Hospital	3,000
Royal Waterloo Hospital for Women and Children	500
Samaritan Free Hospital for Women	800
South London Hospital for Women	800
University College Hospital	12,000
Total	£87,900

Higher Contributions for Health Insurance Dropped.

Mr. J. H. Thomas asked the Minister of Health, on Tuesday, March 7th, whether it was his intention to proceed with the bill increasing National Insurance contributions.

Sir A. Mond answered that in view of the objection to increasing such contributions in present circumstances he had obtained the concurrence of the Consultative Council on National Health Insurance in securing the economies in State expenditure on National Insurance recommended by the Geddes Committee, with certain other economies, on lines different from those suggested by the Committee. The proposal was that all State expenditure on National Health Insurance, with certain exceptions such as the cost of the central administration, the cost of audit, and the statutory two-ninths contribution, should be defrayed until December 31st, 1923, from the accumulated surpluses of approved societies. This proposal had been accepted by the Government, and legislation to give effect to it was being drafted. Between the present date and December 31st, 1923, the whole position would be reviewed.

The above announcement is in accordance with a forecast made in this column last week.

Criminal Law Amendment Bill.—The text of the Criminal Law Amendment Bill, introduced by the Home Secretary on February 8th, has been issued. It contains six clauses and a schedule. The principal proposals are that consent shall be no defence to a charge or indictment for an indecent assault on a child or young person under the age of 16, and that reasonable cause to believe that a girl was of or above the age of 16 shall not be a defence to a charge under Sections 5 or 6 of the Criminal Law Amendment Act, 1885. The maximum penalties imposable on keepers of brothels are to be increased to a fine of £100 or imprisonment with or without hard labour for a period not exceeding three months, and on second or subsequent conviction to a fine not exceeding £250, and to imprisonment with or without hard labour for a term not exceeding six months. In addition to suffering such penalties persons may be required to enter into recognizances with or without sureties to be of good behaviour for twelve months; or in default of entering into such recognizances may be imprisoned for a period of three months beyond the imprisonment already awarded. For Scotland different provisions are proposed. Indecent conduct which would constitute an offence in common law in reference to a girl under the age of 12 is to be reckoned in the case of an offence under the present measure, when a girl is between 12 and 16 years of age, whether with consent or not, and the offender is to be liable—on conviction or indictment—to imprisonment with or without hard labour for a period not exceeding two years, or on summary conviction to imprisonment for a period not exceeding three months. The penalties on conviction of brothel keepers are also changed. Another section of the bill proposes the repeal of the Punishment of Incest Act, 1908, which requires that all proceedings under the Act shall be held *in camera*.

National Insurance Funds.—At the instance of Mr. Rhys Davies, on February 28th, Sir A. Mond said that the total loss suffered in National Health Insurance funds by the conversion or sale of Consols and other securities purchased previously to December 31st, 1921, was approximately £1,800,000. The extent of the depre-

ciation of securities held on December 31st, 1921, was approximately—on the basis of mid-market prices—£2,100,000. The amount of interest earned by the investment through the fund of moneys standing to the credit of approved societies on December 31st, 1921, was approximately £10,000,000, and the proportion credited to the societies £7,500,000. While the improvement in market prices went far to meet the losses and depreciation mentioned, it rendered the maintenance of the existing average yield more difficult, since new moneys had to be invested on less favourable terms.

Increase of Sickness amongst Insured Persons.—Sir Robert Clough inquired, on March 9th, whether the medical reports and statistics available in connexion with the National Insurance scheme indicated that any increase of sickness, particularly among women, was due to the prevalence of restricted means of livelihood arising from unemployment. Sir A. Mond said that the figures available as to the claims for sickness benefit amongst approved societies comprising about half the total number of insured persons showed that there was an increase in the number of weeks for which benefit was paid in 1921, as compared with the previous year, of 1.4 per cent. in the case of men and 8.4 per cent. in the case of women. Many factors must, however, be borne in mind in making a comparison between the figures for the two years and, in particular, the serious epidemic of influenza about the end of the year 1921. The material in the possession of the Ministry did not make it possible to state to what extent the increase might have been attributable to the cause referred to by Sir Robert Clough.

Irish Insurance.—Mr. Devlin, on February 27th, moved an address praying that the Order in Council dated January 31st, 1922, and cited as the Government of Ireland (Adaptation of Health Insurance Act) Order, 1922, be annulled. His complaint was that the British Government was handing over to the Northern Government the health services before the Southern Government had begun to function, and that according to the Act the transfer should be made simultaneously. Sir Hamar Greenwood, in reply, maintained that the action being taken was absolutely correct, and, indeed, was necessary in the circumstances. The staff in Northern Ireland was complete, ready to take over duties on March 1st; and so there would be no serious break in the administration in the North of Ireland. No more serious inconvenience would be caused in administering the Health Insurance Act by the Northern Parliament on the one side, and by the Southern on the other, than occurred in administering the Act in Wales on the one side, and in England on the other. Captain Redmond urged that it was wrong to divide an Act which was based upon area administration before the area itself had been properly defined. Mr. Devlin's motion was counted out.

Pensions Appeal Tribunals.—The Solicitor-General, on February 28th, moved a vote for a supplementary sum not exceeding £5,000 for salaries and expenses of pensions appeal tribunals. He explained that the original estimate provided for only nine tribunals, but in face of arrears it had been found necessary to increase the number to twenty-four. By the end of last year the accumulation had been cleared off, and four tribunals had been demobilized, but it was necessary at present to maintain twenty. Mr. Lawson moved a reduction of the vote by £100, on the ground, not that the additional tribunals were unnecessary in the existing circumstances, but because, in his opinion, if the Medical Boards and the Pensions Minister did their work rightly, cases which went to the Appeal Board would be settled. The Solicitor-General, replying to a rather discursive debate, promised that careful consideration should be given to the views expressed in favour of opportunities for a rehearing of appeals in particular cases. The vote was carried by 160 to 59.

Medical Treatment of Ex-Service Men.—Mr. Will Thorne, on March 1st, raised the case of casual dock labour, ex-service men, who need to attend a hospital and other institutions for treatment and cannot get allowances for expenses and loss of time—such loss of time arising because they have to be at a place of call for employment every morning. Mr. Macpherson agreed to meet the exceptional position by accepting the required certificate from the pensioner's usual employer, instead of, as in other cases, from the actual employer; a further relaxation of the rules was not thought practicable.

Appeal Tribunal Statistics.—On request by Sir R. Clough, the Minister of Pensions, on March 1st, gave the following statistics of the number of appeals finally rejected by the Pensions Appeal Tribunals for England and Wales, and the percentage they represented, in each of the last four periods of three months:

Period.	No.	Percentage.
February-April, 1921	3,981	71.5
May-July, 1921	7,351	72.0
August-October, 1921	7,943	72.2
November, 1921-January, 1922	8,173	72.4

Conditional Pensions.—Major Tryon, answering a question by Mr. Gillis on March 6th, said that the personal and family allowances and other privileges granted under Article 6 of the Royal Warrant in respect of ex-service pensioners were in all cases conditional on the acceptance of the course of medical treatment which was considered necessary by the medical advisers of the Ministry. The Pensions Minister had to consider whether they could be continued at full rate where a course of treatment was interrupted against definite medical advice to the clear detriment of a man's condition.

Tuberculosis Cases.—In reply to Sir James Butler, Major Tryon, replying for the Pensions Minister, said that the provisions made for ex-service men suffering from tuberculosis were not only adequate but exceptional. Generally speaking, in every active case of tuberculosis the man received the equivalent of pension at

the maximum rate, and where a pensioner had satisfactorily completed a prescribed course of treatment and training pension at 100 per cent. rate was granted for six months, followed by at least 50 per cent. for the next two years.

The Burden of Income Tax.—Dr. McDonald inquired, on March 1st, if the Chancellor of the Exchequer would endeavour in the next Budget to reduce the income tax by at least one shilling in the £, and so lessen the heavy burden borne by all taxpayers. Mr. Hilton Young said that the Chancellor of the Exchequer was not in a position to anticipate his Budget statement. Dr. McDonald asked if the Chancellor would apply the principle of the equality of the sexes to the incomes of husband and wife, taxing each separately according to individual means. Mr. Young responded that full recognition of the principle of equality was afforded by the provision by which either husband or wife could elect to have separate assessment. The Chancellor could not agree to the suggestion for separate ratings, as that would shift burden from the rich to the poor.

Pure Milk Supply.—In reply to a suggestion by Mr. Hurd, on March 1st, that a small committee should be appointed to consider the simplest means of ensuring the cleanliness and purity of the milk supply of urban areas, with a view to the amendment of the Act of 1915 before it was brought into operation, Sir A. Mond said he was in continual consultation with persons well qualified to express opinions, and was now considering the introduction of legislation. Viscountess Astor inquired whether, if proposals made by influential producers and distributors were put into an Act, towns would be able to adopt model clauses which would enable them to improve the milk supply at little cost to the taxpayer. Sir A. Mond said he thought that the bill now being prepared would meet the general view, and he would see, if possible, that it should cast no burden on the ratepayers.

Foot and Mouth Disease.—Major Barnston, in answer to Mr. Doyle on March 1st, stated that, as no method could be discovered of cultivating artificially the virus of foot-and-mouth disease or of identifying it, the inquiry into the means by which the infection causing sporadic outbreaks of this disease was carried had been discontinued. Circumstantial evidence pointed to the air or birds as the most probable carriers of the disease. The Minister of Agriculture, as already stated, was endeavouring to arrange for an international inquiry into the whole subject.

Veneral Disease.—Captain Elliot asked, on March 1st, what grants were being paid direct by the Ministry of Health to the National Council for Combating Venereal Diseases, and what, through the local authorities, on the 75 per cent. proportion of sums expended by them. Sir A. Mond said that the amounts paid up to date to the National Council for Combating Venereal Diseases during the current financial year amounted to £9,500. No grants were made direct by local authorities to the National Council.

Cancer Investigation.—Mr. T. Griffiths asked, on March 2nd, whether, in view of the increase in mortality from cancer and the urgent necessity for investigating the origin of the disease and the best form of treatment, the Prime Minister would consider the advisability of the appointment of a Royal Commission. Sir Alfred Mond said he was advised that a Royal Commission would not be a suitable body to undertake an investigation of this kind. Extensive research into the cause and treatment of the disease had for some time past been undertaken by various competent medical bodies in this and other countries.

Coroners Emergency Provisions Bill.—This measure received the Royal assent on March 2nd.

Clinical Thermometers Bill.—The bill introduced in the Lords had its third reading and was passed through that Chamber on March 1st.

Answers in Brief.

There are 302 ex-service men under notice of discharge from the

and surgeons' lobby, with separate dressing rooms, has been equipped in ramothry of Mrs. Martindale, who was the first to originate the idea of a Sussex Women's Hospital officered by women physicians and surgeons.

COURSES ON TUBERCULOSIS AT MANCHESTER.

The regulations for the curriculum as well as the examinations for the diploma in tuberculosis of the Welsh National School of Medicine were published in our issue of February 25th, 1922 (p. 333). We have now received particulars of the advanced courses on tuberculosis instituted by the University of Manchester in 1912, in connexion with the course for the diploma in public health, by the late Professor Sheridan Delépine, who described their purpose in our columns in January, 1913. The acting director of the public health laboratory at Manchester informs us that owing to the war those courses had been interrupted, but that the certificate has been obtained by some sixteen medical practitioners, the majority of whom also held the D.P.H., at Manchester. The course extends over a period of not less than six months, and includes laboratory practice, supplemented by demonstrations and lectures at the public health laboratory; instruction in administration at health offices recognized by the university; and clinical instruction at tuberculosis dispensaries, hospitals, and sanatoriums recognized by the university.

INSPECTION AND TREATMENT OF LONDON SCHOOL CHILDREN.

Under the London County Council system of medical inspection, children requiring treatment or observation are re-inspected about six months after the first inspection, and, if necessary, a second reinspection takes place at the end of a further six months. In 1921 the number of children examined in detail at elementary schools was 294,552, of whom 113,732 (or 38.6 per cent.) were noted as requiring treatment for one or more defects; teeth, vision, and nose and throat complaints accounted for most of these cases. In addition to the elementary school examinations, 2,255 children were examined at special schools, of whom 40.6 per cent. were found to need treatment for defects other than the disability which rendered attendance at a special school necessary; and 73,470 children were seen during the year as urgent cases, either at the schools, treatment centres, or local offices, and 26,425 of these were found to require treatment. At a first reinspection of children marked out for review there were 112,776 cases, of which 45.2 per cent. were regarded by the school doctors as discharged, and of 62,320 cases which came under the second review the school doctors reported that 60.3 per cent. had received treatment or no longer needed it. The results of the year 1921 are the best since the Council undertook the inspection and treatment of children. The report of the Education Committee states also that of every 100 cases receiving treatment 73 receive it under the Council's scheme, and the remaining 27 go to private practitioners or dentists or to hospitals under the scheme. The full average cost of treatment is charged to the parents of fee-paying pupils in secondary schools who cannot afford to make private arrangements, and these charges, representing the cost of the treatment to the Council, are to be, for 1922-23, in the case of enlarged tonsils and adenoids, 9s. 8d.; minor ailments, 8s. 1d.; dental treatment, 7s. 2d.; x-ray treatment of ringworm, 25s. 4d. These rates show a reduction of 1s. 1d. and 5d. for minor ailments and dental treatment respectively.

RE-EDUCATION OF TUBERCULOUS EX-SERVICE MEN.

Dr. Noel Bardswell has submitted a report to the London County Council on an inquiry into the results of combined courses of treatment and training of tuberculous ex-service men. The report relates principally to the experience of ex-service men sent to training centres from the various metropolitan boroughs. During the period 1918 to 1921, 160 London men passed through the training centres at Papworth Colony, Nayland Colony, and elsewhere, but so far as could be ascertained not one of the men discharged home is now employed at the occupation for which he was trained. Some made an attempt to benefit by training, but failed for various reasons. Only nine men are employed in any newly acquired calling, twenty have resumed their original occupations, and the remainder—about 130—are unemployed and living on their pensions. The report submitted by Dr. Bardswell is believed to represent the first attempt by any public authority to ascertain the results of the scheme for the vocational re-education of tuberculous persons. The results are admitted

England and Wales.

NEW SUSSEX HOSPITAL FOR WOMEN AND CHILDREN.

THE *Quarterly News-letter of the Medical Women's Federation* for February, 1922, contains an account of the opening of the new buildings of the Sussex Hospital for Women and Children, which, after having for some years carried on its work in temporary premises as a branch of the Lady Chichester Hospital, was opened by Lady Astor a short time ago. The new buildings comprise a large outpatient department, with waiting rooms, examining rooms, dental department, and venereal diseases department. There are two wards, each containing eight beds, for medical and surgical cases, into which patients are admitted at a minimum weekly charge of one guinea, and in addition there are ten private wards accommodating twelve or fourteen private patients, who pay from two to seven guineas a week. The operating theatre, with anaesthetizing room, sterilizing room,

July, 1,831; in August, 1,952; in September, 2,751; in October, 2,615; in November, 2,502; in December, 3,040. Total, 27,410.

to be discouraging, but it is thought that the selection of cases for training is open to improvement; and it has also to be remembered that the experiment has been carried through at a time of exceptional difficulty, particularly as to the subsequent employment of those who have been trained.

REPORT OF THE CITY OF LONDON CORONER.

In his annual report for 1921, as coroner for the City of London, Dr. F. J. Waldo states that 570 inquests were held during the year, and that *post-mortem* examinations were carried out in all save 17 of the inquiries. Public inquests with juries numbered 305, the remaining 265 being investigated by the coroner without a jury. Dr. Waldo states that in all cases of violent death he is still a believer in the constitutional method of the coroner sitting in public with a jury, on the principle that an intelligent jury, as found in the city, directed by a coroner, is a better and more satisfactory tribunal in the public interest for the elucidation of truth than that formed by a coroner sitting alone. In his opinion, also, inquests are a mere farce without *post-mortem* examinations, and he thinks that inquests ought to be left alone altogether if not carried out in a thorough manner.

THE BRITISH INDUSTRIES FAIR.

The British Industries Fair, organized by the Department of Overseas Trade, has been held during the last fortnight at the White City, London. In a dozen large halls, accommodating altogether the exhibits of well over a thousand firms, almost every British product, from safety razors to aeroplanes, has found a place. From the medical point of view the exhibition was of interest on many sides, for it included a brave display of fine chemicals, alkaloids, disinfectants, surgical and dental apparatus, orthopaedic appliances, hospital furniture, opticians' supplies, and exact instruments for the laboratory, but even though the exhibits were classified to some extent, so that one went into one hall to look for miners' lamps and to another at half a mile distance for vaccines, the task of anyone who should attempt to describe the exhibition in detail would be stupendous. Here were twenty firms showing analytical and research chemicals, a number of others concentrating on sanitary preparations and druggists' sundries, and others again on perfumery and cosmetics; the chemical section, with its pyramids of salicylate and aspirin, and such objects of interest as the Burroughs Wellcome exhibit of the stages in the preparation of kharsivan, was very wonderful and engrossing. It was very closely rivalled, however, by the glassware section, for glass-making, both for artistic and scientific ends, is progressing quickly, and offers another illustration of British energy and resource in the face of no small difficulty.

CENTRAL MIDWIVES BOARD.

At a meeting of the Central Midwives Board for England and Wales, held on February 23rd, Sir Francis Champneys presiding, four midwives were struck off the roll. The chairman announced that the following had been re-elected as representatives on the Board by their respective bodies: Sir Francis Champneys (Royal College of Physicians of London); Dr. Griffith (Royal College of Surgeons of England); Dr. West (County Councils Association); Dr. Fairbairn, Miss Pearson, and Miss Pollard (Incorporated Midwives Institute); Mr. Sangster (Society of Apothecaries); Professor Briggs, Lady Mabelle Egerton, Miss Haydon, and Miss Le Gent (Ministry of Health). Letters were read from the town clerks of Bristol, Portsmouth, Stoke-on-Trent, and West Ham stating that their respective authorities support the action of the Manchester City Council in objecting to the carrying and distribution by midwives of preparations containing opium. It was resolved to forward to each authority a copy of its resolution on the question passed on November 17th, 1921.

Scotland.

GLASGOW ROYAL ASYLUM.

In his annual report Dr. D. K. Henderson, physician superintendent of the Glasgow Royal Asylum, stated that of the 151 new patients admitted during the year 92 were women. This predominance of the female sex, which had been observed during the past two years, was, Dr. Henderson suggested, to be explained partly as a reaction from the strain of the war years, and partly as the result of the high cost of living and the difficult economic and social conditions of life

in these days. An interesting feature was the large proportion of voluntary cases (39 per cent. of admissions), which evidenced that the public was realizing more and more that the mental hospital was more than a mere custodial institution—it was a real hospital for the care and treatment of patients. The recovery and improvement rate reached 52 per cent., but Dr. Henderson thought that still better results could be obtained if cases applied earlier for treatment. During the year he had introduced a new grouping or classification of mental disorders, to bring it more into accord with modern ideas. He advocated a uniform scheme of classification to be used throughout mental hospitals in order to facilitate ready comparisons in different parts of the country, and so lead to more precise data. In this psychological and psycho-analytic age they realized that mental disorders were not simply characterized by the expression of absurd delusions and hallucinations, or by odd, strange, bizarre conduct, but that these disorders were merely symptoms, the result of unhealthy or disorderly habits of thought which had developed gradually. The disorder was often the expression of a wish which had been unfulfilled. Some individuals, instead of meeting the actual difficulties of life, tended to fly from reality, and, in their mental disorder, seemed to attain those things for which they had been vainly striving in their ordinary conscious life. This same type of mental mechanism was in operation in ordinary life in the group who styled themselves spiritualists. Such were those who, instead of meeting the difficulties of life and facing its various issues with common sense, sought to evade these issues like the patient of unsound mind, and fly to something mystical which they termed a "new religion," and about which they could really know nothing. In his opinion it would be of much more practical benefit to themselves and healthier for others if they devoted themselves to the study of the problems of everyday life, instead of trying to outline a hereafter. He referred to the treatment of epilepsy during the past year by luminal, a drug about the efficacy of which glowing reports had been made in America and in Germany. He considered that the results so far were inconclusive, because the number of cases was too small to allow an opinion to be based on them, but they were sufficiently satisfactory to warrant more extensive trial. The total number of patients under treatment during the year was 648, and the average number of residents 508. Of the 151 new patients admitted, 143 were private cases. Of "service" patients admitted to Gartnavel there had been in all 113. Of these, 14 have been discharged as recovered, 7 greatly improved, 3 not improved; 7 have been transferred to other mental hospitals, and 15 died, leaving 67 still under treatment.

CRICHTON ROYAL INSTITUTION, DUMFRIES.

The report of Crichton Royal Institution by its physician superintendent, shows that 1,242 patients were under treatment during 1921, that the number at the close of the year was 971 (442 males and 529 females), and that there were 636 private and 335 parochial patients. Of the private class 169 were voluntary boarders. Dr. Easterbrook, like Professor Robertson at Edinburgh, emphasizes the value of the early treatment of mental disease, and points out that under the law as it stands only private or "paying" patients can be admitted for treatment in mental hospitals as voluntary boarders; the rate-aided patient must be certified as a "lunatic" and become technically, at any rate, a "pauper" before he can gain entrance; obviously there are some reforms needed to put this matter right and give to rate-aided patients the chance of early treatment on a personal application for admission. The superintendent also pleads for the establishment of mental clinics in the general hospitals of the medical schools and main centres of population in the country as a prophylactic and curative measure for the treatment of incipient mental disease. Further, he points out that the United States with its National Committee for Mental Hygiene (founded in 1909) is far ahead of this country in its endeavour to prevent mental disease by spreading reliable information on the subject, and by trying in other ways to maintain mental health. During the year 77 certificated patients and 7 voluntary boarders died; the causes of death among the certificated were chiefly heart disease and arteriosclerosis, cerebral apoplexy, exhaustion from mental disease, senile decay, pulmonary tubercle, and influenza with pneumonia. In 53 per cent. of the deaths the mental disease had lasted for longer periods than two years.

THE LISTER WARD.

The weekly meeting of the Glasgow Medical Lunch Club was held on March 2nd, the guest of honour being Mr. Ernest Maynard. After lunch he addressed the members on the subject of museums. He referred to the outset to his own interest in, and work connected with, museums throughout a long medical life. He emphasized strongly the instructive and educative part which such institutions play in conveying to the minds of all classes valuable information. He instanced as an example the Hunterian Museum at Glasgow University, a lasting memorial to the name of William Hunter, physician and anatomist, who, by his will in 1783, founded it. From that the speaker proceeded to refer to the proposed Lister memorial, and to that end more especially the retention of the original Lister ward in the Glasgow Royal Infirmary. He recapitulated the various steps which had been taken in the matter from the time when it was first proposed to retain the ward until now, and deplored the lack of wholesome sentiment which had led to the decision for its demolition. As one of those who had all along taken an active part in advocating its retention on its original site, he again made an impassioned appeal against its destruction, as thereby an invaluable asset would be lost to the Royal Infirmary, to Glasgow, and to the medical world. He summed up his appeal thus: "You cannot separate a part from a perfect whole without lessening the relative value of the divided portions. To remove the Lister ward from its inseparable associations with all that has made it and the Royal Infirmary one in the eyes of the civilized world is irretrievably to damage both."

South Australia.

(FROM OUR SPECIAL CORRESPONDENT.)

MEDICAL LEGISLATION.

IN an otherwise somewhat barren session Parliament has passed two Acts of some importance to the medical profession. The object of one is stated in the preamble to be to make better provision for the control and management of the Adelaide Hospital. The present Board of Management is to be replaced by a board of three, the chairman of which must be the Inspector-General of Hospitals. How in addition to his present duties Dr. B. H. Morris will manage to find time to supervise the hospital effectively remains to be seen. Legislators, however, seem to think that the new departure will prevent such incidents as deaths under anaesthesia and the occasional dismissal of a drunken man with an unsuspected fracture of the skull. Besides the trimvirate (which may include a member of the gentler sex) an advisory committee of seven members will be appointed to assist and advise the University Council and the Hospital Board as to appointments to the staff and other matters affecting the Medical and Dental Schools. The Act thus recognizes the importance of the hospital as a teaching school, whereas formerly the students were considered to be there very much on sufferance.

A short Medical Practitioners Amendment Act was also passed; the essential point in it is the power given to the Medical Board to establish reciprocity, and the adjustment of fees, with similar Boards in the adjoining states, as well as with the General Medical Council, if it be possible. At present an Adelaide graduate, who pays 5 guineas for perpetual registration, has to pay additional fees for permission to practise in other states, and, if he should go to England for six months to finish up his work, he must pay another £5 for registration there, although he never intends to stay to practise.

Although the profession seemed inclined to boycott the Opticians Act, two distinguished specialists have been persuaded to join the Board and the examinations have commenced. The Nurses Board, under the new Act, has also come into existence, and is busy formulating rules and registering the old hands. The Venereal Diseases Act appears to be a dead letter at present, as no regulations have so far been gazetted.

THE UNIVERSITY.

Sir Joseph Verco has decided to retire from some more of his activities. He has refused reappointment (for the eighteenth time) as President of the Royal Society of South Australia, and he has also declined to be renominated as

Dean of the Faculties of Medicine and of Dentistry, in which capacities he has rendered yeoman service to the University. He is succeeded as Dean of the Medical Faculty by Dr. W. T. Hayward, C.M.G. At the Adelaide Hospital the teaching staff is strengthened by the appointment of Dr. William Ray (a former Rhodes scholar) as full physician, though the retirement of Dr. H. Swift will be a distinct loss to the students. This year also Dr. T. G. Wilson succeeded to the Lectureship on Gynaecology vacated by Dr. J. A. G. Hamilton, who has retired from practice.

THE BRANCH.

The outstanding features of the year have been the appointment of Dr. Bronis Smicaton as President, the delivery of the Listerian Oration by Mr. Fred Bird, C.B., the distinguished Melbourne surgeon, who took for his subject the knee-joint, and the death of our much-loved and respected colleague, Benjamin Poulton, the originator of the now extinct Inter-Colonial Medical Congress, and a former secretary and president of the Branch.

MEDICAL DEFENCE ASSOCIATION.

At the annual meeting of the Medical Defence Association it was reported that a medical man in the country had been assisted who appears to have been too outspoken in his utterances with regard to the competence of a nurse who ran a hospital in his district. After two days' discussion in the local court, the case was settled out of court. Another case had been mentioned in Parliament and had created much sensation, an unfortunate circumstance which could easily have been avoided but for the indiscretion of the operator who discovered the forceps in the pelvis which had accidentally been left there by another surgeon two years before.

India.

LEPROSY IN BENGAL.

THE Bengal Government has decided to establish a leper settlement for 1,000 persons. The settlement will be situated at some distance from one of the larger towns, and it will be attractively laid out. At present there is no question of compulsory segregation of any but pauper lepers in this colony, so that difficulties which might otherwise arise will be obviated. The cost will undoubtedly be great, but the value to the sufferers and the population will, it is anticipated, more than compensate for the expenditure. This action is none too soon, as the Collector of one district described as the "blackest spot of leprosy in India" gives an appalling description of the conditions which now exist under the present futile attempt at prevention and segregation. Leprous mendicants are at large everywhere, and many known lepers ply trades which, in the interest of public safety, are forbidden by the Lepers Act. This is not peculiar to this part of India; it is not remarkable that credible authorities state that leprosy is spreading from the lower to the middle classes. It is hardly realized in England that it is not uncommon for lepers to be present at village feasts, to sit on the common mat, and to share the same hookah with healthy individuals. They actually wash in the village tank, and, of course, freely handle the coins and paper money circulating in the shops.

INDIAN MIDWIFERY TRAINING.

The response made by the General Council of Medical Education and Registration to the representations of the Secretary of State and Government of India shows, says the *Civil and Military Gazette*, that that body had not been actuated by malice and uncharitableness and racial prejudice as certain speakers in the Legislative Assembly appeared to imply during the debate on the question last September. It could hardly be denied that there were valid grounds for its conclusion that the practical training in midwifery in Indian medical colleges fell a good way short of the required standard. By agreeing to postpone its final decision on the question of recognition of Indian medical diplomas the Council indicated, it might be assumed, that it was prepared to take the special circumstances obtaining in India into account. It was admitted that the customs of the country, except possibly in Madras, made it difficult for Indian medical students to obtain much practical experience of midwifery cases. Even allowing for this difficulty, however, the Council would be sure to ask for definite evidence that the medical

colleges in this country had made genuine efforts to improve the standard of training in midwifery by every possible means before it consented to continue recognition of Indian medical diplomas.

A CHRISTIAN UNIVERSITY IN INDIA.

The directors of the Forman Christian College, Lahore, which is the largest missionary college in northern India, with the largest number of scholars among the colleges of the Punjab University, have very strongly urged the scheme for a united Christian university for the Punjab. In order to consider practical proposals a conference has been arranged between the board of directors of the Forman Christian College, representatives of the Indian Christian Association, the American missions, the Church Missionary Society, the Scots Church, the Methodist Mission, and some educational experts.

LIQUOR REFORM IN BOMBAY.

Among the regulations made by the Bombay Government to control the consumption of alcohol and to discourage excessive manufacture and sale of illicit spirits, is one which fixes the maximum quantity of "country spirit" which can be possessed by or sold by retail to one individual at a time. The maximum hitherto has varied in different parts from one to seven bottles. The Government have now decided that the quantity should be reduced to one bottle in all urban and municipal areas; and as regards most rural areas where shops are at a considerable distance, three bottles.

Correspondence.

THE HUNTERIAN LECTURE ON PROSTATIC ENLARGEMENT.

SIR,—I have read this lecture by Professor Kenneth Walker, published in the *BRITISH MEDICAL JOURNAL* on February 25th, with much interest, partly because it contains much new matter resulting from his valuable original investigations, and partly because he arrives at practically the same conclusions as to the pathology of the complaint that I did in 1910.

As my views were quite original I looked for some acknowledgement, but failing to find it I write to call Professor Kenneth Walker's attention to my paper read at the Liverpool Medical Institution, and published in full in the *Liverpool Medico-Chirurgical Journal* for July, 1910, and also in the *Lancet* for July 30th, 1910, with ten illustrations.

To show how similar Professor Walker's views are to those I had published, I append a copy of his printed conclusions and my own:

"(1) It is impossible to explain enlargement of the prostate by any theory of chronic inflammation alone.

"(2) Although enlargement may reproduce conditions favourable to the development of a neoplasm, the enlargement itself does not come into the category of true tumours.

"(3) The condition is in the nature of a fibro-epithelial degeneration which finds its analogy in the female sero-cystic disease of the breast.

"(4) This degeneration may be regarded as an accident occurring during the progress of involution of the genital tract.

"(5) The cause that determines the onset of the condition is unknown, although it is not improbably connected with a loss of endocrine balance occurring during this period."

"(1) The accepted theories as to the cause of prostatic hypertrophy all fail because each can only apply to a limited number of cases.

"(2) The prostate and breast are both controlled by their respective dominant sexual glands, and respond to their influence in a similar way in health and disease.

"(3) Both organs are subject to a disturbing influence at the climacteric period, which may, and frequently does, result in hypertrophic change.

"(4) In such change the microscopical appearances in the two organs show a remarkable resemblance in all essential details.

"(5) Prostatic hypertrophy, like the mammary involution hypertrophy, occurs only at the climacteric period, whereas there is no known neoplasm which is so strictly limited to an age-period.

"For these reasons I consider prostatic hypertrophy is not due to a chronic inflammation of septic or specific type, nor to a neoplasm, but that it is an involution change similar in character to that with which we are familiar in the mammary gland."

—I am, etc.,

FRANK T. PAUL.

Liverpool, March 6th.

SIR,—I have read with interest Professor Kenneth M. Walker's lecture on the nature and cause of old-age enlargement of the prostate (February 25th, p. 297), and am pleased to find that his accurate researches do not give the lie direct to the position in which I find myself as regards the above subject as a general practitioner.

I think it is now almost universally admitted that the thyroid enlargement of young women is the response, in the first place, of the organism to the call for increased function. Since, in 1904-5, I successfully treated over a hundred young women with early soft parenchymatous goitre by the patient administration of small doses of thyroid extract, I have never had reason to alter my opinion that in the pathogenesis of goitre physiological hypertrophy plays a part. It has become a working rule with me that early enlargement of any gland connected with the endocrine system is a call for increased function, and I have applied it in the case of the early enlarged prostate. So I have given "Opocaps" prostate gland gr. 3, prepared by the British Organotherapy Co., in a few of these cases. It is no good giving thyroid extract to people with enlarged thyroids of long standing, and, similarly, the enlarged prostate must be in an early stage of physiological hypertrophy, such as, I submit, precedes formation of the so-called adenomata.

My contention is upheld by the fact that these people get relief from prostatic feeding. I have two men under my care—one a writer by profession, and the other an overwrought mechanic—who both have taken repeated courses of the preparation named. The first begins with his capsules when he feels the return of frequency and slight difficulty in micturition, and has been going on like this for two years. The second had persistent haematuria, copious and clotting, six months ago, for two weeks. He says that micturition is becoming increasingly easier as he goes on with the treatment. The clinicians threw more light on the thyroid function than the researchers, and I should be much obliged if your readers who have used this remedy in really early cases where it is likely to do good would let us know their opinion, thus upholding, or the reverse, my—may I say?—analogical guesswork, that physiological hypertrophy plays a part in, or possibly is the main prime cause of, enlarged prostate.—I am, etc.,

Heaton, Bradford, Feb. 28th.

A. F. MARTIN, M.D.

HAEMORRHAGIC COLITIS.

SIR,—The article under this heading by Mr. Geary Grant (February 25th, p. 308) raises a subject of particular interest. There can be no doubt that haemorrhagic colitis is a very definite form of colitis which often goes unrecognized. I gave a full description of the condition in my *Diseases of the Colon*, published in 1910, but there have been very few recorded cases since then, although at St. Mark's Hospital we get three or four cases yearly. Records of five cases are to be found in the *Transactions of the Proctological Subsection of the Royal Society of Medicine* (November 12th, 1913).

The two cases described by Mr. Grant are typical. Both were in young adults, the bleeding was profuse, and there was a serious anaemia; there was no pain, temperature was raised at night, and the patients became seriously ill.

The condition is easily diagnosed by means of the sigmoidoscope. In my experience no other condition imitates the appearance of the mucous membrane seen in this disease. Repeated bacteriological examinations have so far failed to demonstrate any specific organism, though in two cases an almost pure culture of *Diplococcus pneumoniae* was demonstrated in the discharges.

Mr. Grant says that in another case he would perform appendicostomy if the patient did not respond to medical treatment. I would advise him to do appendicostomy at once, as I have never seen any case recover from medical treatment, and it is most important that the appendicostomy should be done as early as possible, and not as a last resort, as is too often done. Appendicostomy is a life-saving operation in these cases, and should be performed directly the diagnosis has been established. As soon as the colon can be kept washed out from the appendicostomy opening the patient begins to recover and progresses with surprising rapidity. I differ from Mr. Grant as regards the method of closing the colostomy. Extraperitoneal methods of closure are uncertain and liable to cause subsequent trouble; resection and intraperitoneal closure is the better method, and should be quite safe where an appendicostomy opening already exists.—

I am, etc.,

London, W., Feb. 28th.

J. P. LOCKHART-MUMMERY.

FATS AND GOITRE.

SIR,—Colonel King (February 18th, p. 287) suggests that there are several localities in England where research on simple goitre could be undertaken, and mentions recruiting areas indicating that certain areas near Chester are endemic areas. One district of Cheshire is also referred to in Hirsch's *Geographical and Historical Pathology*.

As children are not exempt, the reports of school medical officers might be of value in determining areas of extraordinary prevalence. Some years ago, when a school medical inspector in Cheshire, covering the middle third of the county from north to south, I was greatly struck with the prevalence of simple goitre in some localities. To avoid the difficulty of deciding whether or not a thyroid was pathologically enlarged, I registered every case in which the outline of the gland was obvious on inspection, and the percentage among the children examined varied from nil in some areas to a maximum of 60 in one small school. I found definite area of maximum prevalence, crescent-shaped, south of Nantwich, one horn of the crescent north-west of Nantwich, the other east of Crewe, with a second area of less intensity extending from Winsford eastwards to near Congleton. From my observations among parents, and from inquiries, adults appeared to be also particularly affected in these regions.

I regret that I left the district before completing what to me was a most interesting study.—I am, etc.,

C. R. GINSON,
M.O.H. Guisborough, Yorks.

February 21st.

PREVENTION OF VENEREAL DISEASE.

SIR,—In the *British Medical Journal* of February 18th (p. 288) Mr. E. B. Turner and Mr. Charles Gibbs ask us to answer eleven questions:

1. Sir Archdall Reid cannot give "the total admissions to hospital of venereal cases under his charge before as well as after he initiated his plan of disinfection at Portsmouth." Before the date of initiation venereal disease had no special interest for him, and he kept no records. Doubtless, however, evidence exists which would furnish not only the information desired, but also material for testing every statement made by Reid—(a) the records of Hulsea Hospital to which all his venereal cases were sent, (b) the monthly reports of his A.D.M.S., and (c) the sick reports made daily to the officers commanding the troops in his medical charge. At first his cases were numerous, and for that reason he initiated his plan. The troops in his charge were throughout of exactly the same type as the rest of the garrison, and presumably suffered equally. In the year the plan was put into operation the general garrison rate of infection was 92 per 1,000. His own rate was 1.5. At a later date he offered to go at his own expense to any area in the kingdom in the confident expectation that he would be able to reduce considerably the incidence of venereal disease. Still later he offered, again at his own expense, to go to any port where men on leave from the Continent landed. Neither offer was accepted; but at least both afford evidence of willingness to put his plan to very stringent tests. Yet later he offered to go to the Rhine. This time the offer was accepted, with the proviso that he should work as a civilian. He was strongly advised by military officers of high rank to decline, as, without a sufficient military status, he would be powerless.

2. Reid cannot "indicate how many men from Portsmouth during the period of his experiment were admitted to other hospitals for venereal disease contracted while in Portsmouth." But to the best of his knowledge and belief, not one man. Certainly not one of his men. It was in orders that all venereal cases must be sent to Hulsea Hospital. They would not have been accepted elsewhere. Nor can Reid say "how many men consulted private practitioners." The question is ridiculous. How should he know? Is there any reason for thinking that a greater proportion of cases consulted private practitioners in Portsmouth than elsewhere? Reid constantly impressed on his men the truth that they were not likely to receive such excellent treatment from private practitioners (including himself) as from the very competent specialists at Hulsea.

3. The evidence on which is based the statement "that throughout the Portsmouth area disease fell to the vanishing point" is contained in the weekly returns compiled for his own information by the A.D.M.S. of the area while testing the plan. Doubtless these returns are still in existence. In

them disease locally acquired was carefully distinguished from that imported by immigrant troops. One of us has begged unavailingly for the publication of these returns.

4. This question involves a misstatement. We never said that Metchnikoff's method of aborting syphilis was particularly effective for prevention. In our opinion the quick use of any active antiseptic is better. We said only that his method, though already employed for prevention by Continental armies and the British Navy, was ignored by a Royal Commission appointed to study prevention. Either the Commission was ignorant of the method, or it wilfully ignored it.

5. We know nothing personally about venereal disease in Germany. But we ask on what evidence is founded the statement that there has been "six years of propaganda in Germany on the lines suggested by the Society for the Prevention of Venereal Disease"? Again, what is the evidence that (a) juvenile disease has increased in Germany (b) because juveniles have been taught to disinfect themselves? We understand that one gentleman from one town in Germany has stated that juvenile disease has increased in his town. He is a warm sympathizer with the N.C.C. and appears to copy its methods. Are there no other conditions in Germany (and Russia) which would account for the increased juvenile immorality and disease? In scorn of the N.C.C. and the Ministry of Health, more than a score of English boroughs have adopted the teaching of quick disinfection. We hear of no increase of juvenile disease in them.

6. We have already explained why it was thought hopeless to bring the question of prevention before the Royal Commission which began work in 1913. Neither of us gave evidence before it; but one of us who was a member of the N.C.C. resigned his membership after becoming aware in 1916 that the question of self-disinfection in men had been excluded from the deliberations of both the Royal Commission and the N.C.C. Before he took further steps in January, 1917, to bring the question before the public, he asked personally for the support of the ex-chairman of the Commission, of the Director-General of the Army Medical Services, and of a distinguished medical member of the N.C.C.; but his request was declined on the general grounds that public opinion would be hostile to such a movement. The S.P.V.D. has since proved the contrary.

7. Certainly we can explain why we "ignore salvarsan treatment as a factor in the reduction of the venereal disease rate which is apparent in the army and navy statistics of all countries from 1913 onwards, but is claimed by them to be entirely due to self-disinfection." Salvarsan has no influence on gonorrhoea which furnishes the great majority of cases. It may cure, but does not prevent even syphilis. The venereal rate of armies is calculated not on a basis of "constantly sick" but on the rate of infection. While the military rate was falling disease was steadily rising among civilians, from whom soldiers derive their infections. How, then, can salvarsan have influenced the rate of infection?

8. Certainly again we are willing to submit our figures "to the analysis and criticism of an independent expert." Indeed, we have been shouting from the house-tops for just that kind of inquiry for the last four years. But even hostile "experts," even the ingenious statistician of the Ministry of Health, with all the evidence at his hand, have been discreetly silent. What, however, does this question mean? Our statements are founded on published accounts—for example, those by Sir James Barrett—all of which can be verified from the records of naval or military units. Is it suggested that the officers who made these easily tested statements were lying? The expert is welcome to the records.

9. This question has already been answered in our previous letter.

10. We would suggest that posters be exhibited in public lavatories warning the public against contagious disease, and when endangered to disinfect with speed and such care that the disinfectant shall reach into every cranny of the skin. These posters could be so worded that the innocent boy would think he was being warned against contagious disease—for example, scabies, sepsis—while the intending sinner would know that the advice was directed especially at him. Most men who sin are ready to seize opportunity. They regard a temptation resisted as a temptation wasted. Such people always discuss sexual matters among themselves and would learn what was meant by the posters. We do not for a moment suggest that juveniles shall be "personally" instructed.

11. Of course not. This question is merely rhetorical.

Systematic personal instruction was never given even in the army.

We do not "find it necessary always to impugn the *bona fides* of those who have arrived at different opinions from" our own. We impugn only the *bona fides* of those who have been caught in the act. We gave some examples in our first letter. The following is another characteristic instance:

"With a view of acquiring a full and adequate presentation of the case, the Committee invited medical representatives specially qualified from professional experience, as well as others who had taken an interest in the question, to meet the Committee or furnish them with memoranda of their views. Among those invited to give us the benefit of their experience or advice in this way were . . . Sir J. Barrett." (*Report of Lord Astor's Inter-Departmental Committee*.) "Is the information derived from that tainted source which cooked the statistics for the Inter-Departmental Committee of 1919?" (Archdall Reid, *The Times*, November 18th, 1921.) "I can assure him that all the evidence was examined impartially." (Lord Astor, *The Times*, November 22nd, 1921.) "Lord Astor . . . has since declared that the Committee was quite impartial, and published the statistics as received. But did it publish all the statistics? Did it even ask for them? Why, for instance, was Sir James Barrett's magnificent success, achieved on a grand scale under the most difficult conditions in Egypt among the Australians, not so much as hinted at?" (Donkin and Reid, *BRITISH MEDICAL JOURNAL*, February 11th, 1922.) "I am writing, therefore, to say I did not give evidence before that Committee, that I was not asked to do so, and that no communication from that Committee, either verbal or written, has reached me." (Sir James Barrett, *The Times*, February 21st, 1922.) "The Committee (as they stated) invited Sir James to give them the benefit of his experience and advice. Unfortunately he had already left for Australia, and they could not delay the publication of their report until they received a memo. from him." (Lord Astor, *The Times*, February 27th, 1922.)

It seems, then, that this impartial and candid Committee first invited the leading advocate and most successful teacher of quick dissection to furnish evidence, next it ascertained that he had passed beyond reach, lastly, still in the exercise of its impartiality and candour, it announced that it had invited him. Meanwhile it collected (and published) evidence not of the successes in Egypt and France, but of the failure in England.

Mr. Turner and Mr. Gibbs suggest that self-disinfection did not succeed in Egypt. Let Sir James Barrett speak for himself:

"On the value of prophylaxis being challenged, an examination of those Australian troops who had been supplied with outfits established the fact that out of a group of 200 men exposed to infection only one contracted disease, and he had not taken precautions. In the lecturer's experience primary prophylaxis had been practically certain in its results."

H. BRYAN DONKIN,
G. ARCHDALL REID.

London, March 3rd.

HOSPITAL POLICY.

SIR,—I gravely doubt whether the Leicester motion in its new guise¹ will be more acceptable to lay committees than it was before. Surely also it is futile to set up again the pretence of a fund for altruistic purposes after the frank confession of quite other intentions openly expressed at the Conference in December, 1920, and the candid admission of the chairman of the Hospitals Committee in his letter of December 24th, 1921. In truth, if this money is honestly earned why not pocket it? If it is not, why touch it at all? To all staffs who support this Leicester motion I would address a few plain questions:

1. Do you deny that your hospital appointment has been valuable, giving you opportunities, fame, and experience hardly to be obtained in any other way, and bringing in indirectly considerable income?
2. Do you deny that in consideration of these conspicuous advantages you deliberately undertook to treat the poor in this institution free of charge?
3. Were you say that, having already reaped such benefits, and while still retaining these advantages, you are honestly entitled, without even consulting the other party to the contract, to publicly repudiate your part thereof, merely because, under stress of financial difficulties, it is found necessary to induce a poor man to subscribe 2s. 6d. a week towards the cost of his child in hospital, such sum being less than the cost of that same child at home when in health?
4. Do you consider it compatible with your dignity, and that of your profession, that 3d. of this 2s. 6d. should be weekly divided among the staff?
5. Do you claim your share of tea, butter, and potatoes contributed for maintenance; and if not, why not?

To those who would reply in the affirmative to these inquiries I have nothing to say; to others I would suggest an

alternative procedure by alteration in the suggested scheme as follows:

Section VI, Para. 19a.—"*Free Patients*. Those who can produce evidence that they are unable to contribute more than their bare cost of maintenance, as distinct from treatment."

Section XII, Para. 33.—"In the event of decisions being taken which would lead to patients (other than private patients referred to in Section IX) paying in part or in whole the cost of treatment, in addition to that of maintenance, either individually or by some contributory method, a percentage of all such payments should be passed," etc.

The essential feature of three grades of patients would still be preserved, but there would be more of the "Free" and fewer of the "Tariff" class, and we might still happily retain our title of "Honorary." Also the word "maintenance" is vague enough to allow latitude to suit opinions in various localities. I would reiterate my opinion that before demanding even this concession and, *a fortiori*, before requiring more, representatives of lay committees should be formally consulted. Surely if these gentlemen, who are really the only persons entitled to speak with expert experience and authority upon such a topic, tell us frankly that, in their considered opinion, the Leicester motion would shatter the success of their appeals to the public, wither up subscriptions, and generally knock the bottom out of the voluntary system, it is mere humbug to pretend that we are supporting the voluntary system, while pressing such a demand. Conversely, if they differ from the Cave Committee, and approve the motion, the latter at once gains immensely added prestige.

With regard to para. 34, in view of the wealth recently disclosed, there is much to be said in favour of this motion as regards approved societies, nevertheless, as a matter of justice and policy, would it not be well to confer first with some persons representing them? Their members now number about 12,500,000; they control and dispense millions of money, can influence millions of votes, and bring much pressure to bear on the Minister of Health. Only lately he personally met and addressed in complimentary terms representatives of the industrial approved societies at their annual conference, and they were afforded a reception by the Lord Mayor at the Mansion House. To me it has always seemed a quite extraordinarily unpractical and unbusinesslike arrangement that of the three parties concerned in the practical working of the Insurance Act—the panel doctors, the Insurance Committees, and the approved societies—the panel doctors and the British Medical Association should each have their separate annual conferences, the Insurance Committees and their clerks have each their separate conferences, the industrial societies and the other combined societies have each their separate conferences, and on no solitary occasion should the least attempt be made to bring these various parties together, in order to discuss their mutual and, to a large extent, quite identical interests. Surely a combined conference at least once a year would be useful, and might bring much pressure to bear upon the Ministry in favour of any necessary reform. A friendly discussion of this hospital problem between two of the parties might pave the way to such alliance. "Public authority" would naturally apply both to the State and to county councils, etc., and their cases would come under para. 34, and not under 33, where they are out of place.—I am, etc.,

Chichester, Feb. 26th.

G. C. GARRATT.

A DIPLOMA IN TUBERCULOSIS.

SIR,—In a note on the above subject you characterize as "remarkable" the recent multiplication of diplomas in special subjects. Very regrettable also I think many must feel it to be, and it is satisfactory to see that an acknowledged leader, Sir Robert Philip, is of this opinion. We have already special diplomas in public health, radiology, tropical diseases, ophthalmology, and psychological medicine, and now we hear of the creation of a diploma "in tuberculosis." In spite of the arguments in its favour cited by Professor Lyle Cummins this new diploma would seem both unnecessary and undesirable. May we expect in the future similar diplomas in venereal diseases, dermatology, laryngology, infant welfare, etc., for which there would appear to be equal justification? The unfortunate newly qualified man of the future, instead of occupying those first most valuable years in the acquisition of clinical experience, unhampered by examination requirements, will need to go about collecting such diplomas (each at the cost of a ten or twenty guinea fee) as he may think necessary in the line of practice he is taking

¹ *BRITISH MEDICAL JOURNAL SUPPLEMENT*, February 25th, 1922.

up, or, if he is a candidate for public appointments, as he may consider will most impress the selection committee.

Surely this is a tendency in the wrong direction. What is wanted in medical education? Is it not a training as complete and thorough as possible in general medicine and surgery for every student? The rest is but common sense and experience, of which no cannot have too much, but which no course for a diploma, still less the diploma itself, can give. Tuberculosis is a part—a very considerable part—of the ordinary curriculum in medicine, surgery, and pathology, and should be taught, in relation to other diseases, in general hospitals, and not as though it were something rare and strange. If there is an extra subject in which a special course is desirable for would-be tuberculosis officers, it is in what one may call social science, the machinery of the Poor Law, the complexities of organized charity, the economics of working-class households, and the like. But this most useful branch of knowledge does not appear to be included in the course for the T.D.D. Wales.

I submit that special diplomas in tuberculosis are undesirable for the following reasons: (1) Men wishing to enter the tuberculosis service might be encouraged to concentrate too early on the specialized work for the diploma, to the exclusion of general hospital experience. (2) Students and general practitioners of the future might come to regard tuberculosis as a highly specialized side line, something of a mystery revealed only to the elect, just as public health is looked upon to some extent as the exclusive interest of men holding the D.P.H., whereas it should be the affair of us all. Even now there is a tendency, for which State treatment is doubtless responsible, on the part of some general practitioners, to feel that his responsibilities in a tuberculosis case begin and end with notification. Yet the responsibility for early diagnosis and for the major part of the treatment of tuberculosis rests, and must always rest, with the general practitioner. To him Osler addressed these words: "The leadership of the battle against this scourge is in your hands."—I am, etc.,

Brighton, March 6th.

A. NEVILLE COX.

THE VIRULENCE OF DIPHTHERIA-LIKE ORGANISMS.

SIR,—In the interesting record of work by Dr. Eagleton and Mr. Baxter on the virulence of diphtheria-like organisms (BRITISH MEDICAL JOURNAL, January 28th, p. 139) the results indicate that on morphology alone the *B. diphtheriae* still cannot be determined. These workers include as *B. diphtheriae* (morphologically) eight strains of *B. xerosis* and fifty-three other avirulent strains. No indication is given of what criterion is taken to justify inclusion on morphology. One cannot admit *B. xerosis* on morphological grounds. It bears resemblance to, but is morphologically distinct at all stages and culturally readily to be distinguished from, *B. diphtheriae*. Asserting this, one may ask, what are the characteristics of the fifty-three avirulent strains? May not they also be morphologically distinct when a standard of comparison is adopted? Working on diphtheria in 1908-10, I was accustomed to rely on a standard which I have always attributed to my master, Delépine. This test, which satisfied me as capable of eliminating the (virulent) *B. diphtheriae* from all "likes," was the simple one of comparing the sixteen-hour culture (or subculture) on Loeffler's medium, stained briefly with half-strength Ziehl-Neelsen solution and immediately washed.

I should be surprised to learn that this criterion still allowed the inclusion of 53 avirulent *B. diphtheriae* out of 05 cultures.—I am, etc.,

Riga, Feb. 22nd.

ANGUS MACDONALD.

INFLUENZA.

SIR,—Each influenza epidemic may well be a new disease, of different are the symptoms. It appeared here first in some of the most lonely and out-of-the-way cottages. In almost every case there was a history of a "common cold" for five or six days. Then quite suddenly there were the symptoms of pyrexia, followed in a few hours by intense pain between the shoulder-blades and a brown furred tongue. This pain was described as burning in character, and often overshadowed all other symptoms. Sometimes there was vomiting and diarrhoea. There was generally some cough, but this

seemed a relic of the previous catarrh. Among some three hundred cases there were only ten with serious lung trouble. These had the symptoms of acute lobar pneumonia, but with the physical signs of bronchopneumonia, very like acute phthisis; five ended with crisis, and three died.

The impression left on my mind was that the preceding catarrh was not the influenza but a predisposing cause. I should feel inclined to say, "Don't catch cold, and you won't have the influenza."

Relapses were common, and several took place before the patient had left his bed. Two were in bed with a "common cold" when the influenza attacked them, and many did not go to bed at all, and yet did quite well. There was nothing to show that the lung cases were due to early neglect.

Its sudden appearance in scattered homesteads made a contagion theory difficult. One was inclined to accept the theory that it comes out of the earth periodically. A number of cats died in the village during the epidemic from some unknown cause.

It disappeared as suddenly as it came, but has left a number of patients suffering from brown-furred tongues and loss of taste and smell.—I am, etc.,

Silverton, Devon, March 6th.

O. CLAYTON JONES.

X-RAY TREATMENT OF CANCER.

SIR,—Will you kindly allow me to disclaim the views on the treatment of cancer by x rays attributed to me in the brief summary of my remarks furnished to you and published in the JOURNAL of February 25th (p. 314) on Dr. Ward's paper read at the Oxford Medical Society?

Though I pointed out the dangers of these massive doses on the blood and intestines, I certainly did not express the opinion, nor do I hold such a view, that the Roentgen-Wertheim technique is "much too risky" for the treatment of uterine cancer.

Neither did I express an opinion in favour of the divided dose method for the treatment of cancer, but I pointed out that in non-malignant cases the divided dose method was to be preferred, and quoted in support of this view the valuable statistics published by Bécère of the treatment of uterine fibroids by small and repeated doses of x rays. Bécère has shown that in 400 cases treated by the x-ray sterilization of the ovaries, in 202 cases the periods ceased after twelve applications of these small doses, but in six of the patients thirty one to fifty radiations were required to bring about this result. Now Wintz and Seitz, administering the same dose irrespective of the age of the patient, bring about sterilization by means of a single massive dose of x rays, therefore it follows that in more than half the cases treated by the massive radiation, a dose of x rays of three or four times the necessary strength is administered.

So far as we are able to judge at present it appears probable that the future treatment of cancer by x rays will be by a technique resembling the single and massive dose of Wintz and Seitz, but that non-malignant growths and diseases will be best treated by a radiation of more moderate strength administered in divided doses.—I am, etc.,

Oxford, Feb. 25th.

W. J. TORRELL.

SUICIDE IN BORDERLAND CASES.

SIR,—While it is certain that Dr. S. E. White desires to do everything she can to benefit those who suffer from mental diseases, she has done what can only have the effect of hurting their susceptibilities. As she points out, many of these sufferers are extremely sensitive. With the laudable intention of avoiding unnecessary pain the Government changed the name of a Department to "Board of Control." Dr. White persists in referring to this Department as the "Lunacy Board," although it is now seven years since that title was abolished. This is not a small matter to morbidly sensitive people, and when one is "out" to criticize others and to effect reform, then even small blemishes show up strongly and create an unfavourable impression.

Dr. White, in most praiseworthy fashion, has qualified her original statements regarding suicide and the treatment of melancholia. Should she not now also qualify those regarding the "Lunacy Board"? As they stand, they give to a complete outsider the impression of animus. This is surely detrimental to her great cause.—I am, etc.,

February 25th.

N.D.

THE NAVAL MEDICAL SERVICE.

SIR,—I have no axe to grind and am not labouring under a sense of grievance, but I do think that when we honestly know or believe a system to be wrong it is a duty to say so, and keep on saying so until the wrong is righted. "Experto Crede's" letter interests me. I should like to know how many senior medical officers are being "turned down."

If one had only to consider the future of the Naval Medical Service one could afford time gradually to attempt to instil into red tape the old, old arguments concerning social position and the relative importance of the executive and civil branches; but if a gross injustice is being perpetrated by the Admiralty on old and tried medical officers, I think an immediate explanation is called for. Any conscientious objector during the war could get a question asked in the House; possibly the same privilege could be obtained for those who did their duty.

In my opinion the blending of the Navy, Army—and now Air—Medical Services (as I adumbrated some time ago) is the final solution.—I am, etc.,

Sevenoaks, March 4th.

GERALD SICHEL.

HOLLOW VISCERA AND VESSELS: CURVATURE AND PRESSURE.

SIR,—In connexion with Sir Robert H. Woods's letter (March 4th, p. 370) I should like to ask if, in the consideration of the mechanical efficiency of the hollow viscera, there is not another important factor that must be taken into account—the force of the muscular contraction. Within limits the lengthening of muscle increases the strength and energy of its contraction. To quote from Professor Starling's Linaere lecture (Law of the Heart): "The energy of contraction, however measured, is a function of the length of the muscle fibre." This being so, the tension in the wall of a contracting viscus would not necessarily remain the same. That is to say, t in the equation $2t = pr$ would not be a constant and p would not vary inversely as the radius of curvature. It might not, of course, follow that the lessened energy of muscular contraction would cancel the increased mechanical efficiency due to the increased curvature.—I am, etc.,

Hull, March 5th.

E. E. LASLETT.

ASTHMA AND THE MENOPAUSE.

SIR,—In your issue of January 7th (p. 12), Dr. MacBean Ross gave a very interesting account of a case of asthma and aggravated nasal trouble, following the production of artificial menopause by radium treatment, which benefited markedly by ovarian extract treatment.

Asthma frequently occurs during pregnancy in those who never had it before, as also trouble of the nasal passage, especially hypertrophy of the turbinates. In a paper on the toxæmia of pregnancy¹ I have shown that these conditions are due, not directly to ovarian insufficiency, but to hyperpituitarism, caused by this ovarian insufficiency. As in aeromegaly, hyperpituitarism produces hypertrophy of the mucous membranes of the upper respiratory air passages,² and this is the immediate cause that is responsible for the frequent occurrence in pregnancy of hypertrophy of the turbinates, deafness, intractable cough and asthma.

In Dr. Ross's case, the artificial production of sudden cessation of the activities of the ovaries and of the uterine mucosa brought about a condition analogous to pregnancy with its concomitant tendency to asthma and nasal trouble, and this was the more easily precipitated in this patient as she had a strong predisposition to both affections.

Ovarian hormone, acting antagonistically to that of the pituitary, explains the marked benefit derived by the administration of ovarian extract.—I am, etc.,

S. E. KARK, M.B., Ch.B.

Capetown, Feb. 8th.

TREATMENT OF EMPYEMA.

SIR,—The treatment of empyema is again being discussed in your correspondence columns. It seems evident that the results obtained nowadays are not generally satisfactory. May I once more urge a return to the older method of opening an empyema always well in front of the mid-axillary

line? I am confident that if this old rule were again observed there would be fewer cases of persisting sinns.—I am, etc.,

Bromsgrove, March 5th.

H. CAMERON KIDD.

"SACRACHE."

SIR,—Your reviewer of Dr. F. J. McCann's book in to-day's JOURNAL blames the author for "perpetrating" the hybrid word "sacrache" for "pain over the sacrum."

But Dr. Matthews Duncan used the word, and used it habitually. It is of no new coinage. In his *Clinical Lectures* there is an article on "Sacrache" and backlacho" on pp. 442-3 [in my copy, which is dated 1886]. The volume is dedicated to Sir Clifford Allbutt—too good a master of English to object to a vivid word which sums up much in little.—I am, etc.,

Holmes Chapel, Cheshire, March 4th.

LIONEL JAS. PICTON.

RESUSCITATION AFTER APPARENT DEATH.

SIR,—Whilst I was in practice in Paris I had in November, 1895, the singular experience of bringing back to life a woman who had been apparently dead for two hours, and on three other occasions of snatching from death patients who were apparently dying when I was called in.

The first case, an English lady, Mrs. X., aged 50, was diagnosed to be suffering from cerebral gumma pressing on the optic tract and the front of the medulla oblongata. Hemiplegia and double strabismus, daily increasing in intensity, with asthenia, were the principal symptoms; potassium iodide in a tonic and good food, the treatment. On the morning of her apparent death there were no indications of her approaching end. At 4 p.m. I was hurriedly summoned, as the attendant said she was dying; but for two hours I was not able to leave an operation I was performing. When I arrived at her house at 6.15 I found her apparently dead, and already "laid out." The attendant said soon after the message summoning me had left, the patient had died.

Whenever I visited cases in *extremis* I always carried in my handbag strychnine, ether, caffeine, ergotinine, and syringes, and brandy. In those days adrenaline and pituitrin were not known; at all events opotherapy was in its infancy. There was no doubt about it that the patient was dead, there being no radial pulse, no heart movements, and no respirations, the usual film over the eyes, and the skin greenish-grey, though it was still warm. On this last indication, and also on account of the unexpected death, I resolved to try and resuscitate the patient. I injected 1/60 grain of strychnine under the left breast, thirty drops of ether under the right breast, and twenty of caffeine under the clavicle; after giving a warm enema of black coffee and brandy we chafed the cardiac region, and rubbed the raised limbs from extremities to trunk with hot brandy. Half an hour after, I repeated the injections, and we persevered with the friction, when suddenly the patient moved her foot; and thenceforward colour returned to the skin, the heart and lungs began to work, the film over her eyes disappeared, and in half an hour more she spoke. We removed her to a warm bed and wrapped her in blankets, with hot bottles by her sides, and she lived for twenty-four hours, becoming gradually unconscious two hours before she finally died. I offered to try and bring her to again, but the husband refused. The cause of death was no doubt due to the invasion of the fourth ventricle by the gumma. Unfortunately no *post-mortem* examination was made.

The second case was an Irish governess, Miss R., aged 24, with gastric ulcer, to whom I was called on Christmas Day, 1896. She was said to be "vomiting basinsful of blood." As I ascended to her mother's apartment I met two fellow physicians, who said: "You are too late, she is dying; there is nothing to be done." However, I went in, and found a priest giving extreme unction to the patient. As soon as I was able to examine her I found that although she looked livid, and the film was on her eyes, and there was no reflex, yet there were shallow breathing and an irregular feeble pulse, scarcely perceptible, and the body was still warm. I did for her what I had done for Mrs. X. the year before, with the addition of an injection or two of ergotinine of Tanret, and a teaspoonful of pounded ice mixed with half a teaspoonful of Pond's extract of witch hazel (a teaspoonful by the mouth) every ten minutes. In an hour the rosy colour of the skin reappeared and her heart and lungs began to work, and she spoke. I saw her ten years after and she was looking strong and well.

The third case, Mrs. B., an American lady addicted to alcohol. An enlarged and tender liver, fatty heart, severe dyspepsia, and painful haemorrhagic diarrhoea were her principal symptoms. On the third day after I had been called in I was summoned by telephone to her hotel; her attendant said she had fainted after coming from the closet. I injected ether and strychnine, as the pulse could not be felt, nor the heart beats heard, and respiration was by gasps; the livid appearance of approaching death spread over her face, and I felt sure the shock and weakness resulting from a painful stool, in her alcoholic condition, had been too much for her degenerated heart. I injected under the skin of her abdomen a pint of artificial serum (Hayem's prescription) and repeated that dose and also the other injections ten minutes after, and gradually she came to, and in less than three-quarters of an hour was out of danger. She left Paris a fortnight later on, and I have never seen her since.

¹ South African Medical Congress, October, 1921.

² *Biccl innere Sekretion*, p. 322.

The fourth case: Mlle de S., a French lady, aged 32, had been operated upon for carcinoma of the uterus, and three years after, when I first saw her, there was recurrence of the growth, which had involved the right ovary and spread to the right iliac fossa. One morning whilst lifting a can of water she felt something snap inside the tumour, and although there was not much pain she felt faint. On examination a couple of hours after, I came to the conclusion she was bleeding internally. Her pulse was 100, and of low tension, soft, and regular. I injected ergotamine of Tanret, put an ice-bag over the hypogastrium and right iliac region. I repeated the injection an hour after, but as she became paler and the pulse beat faster, besides giving her a third injection I administered Pond's extract with pounded ice every ten minutes. Four hours after the accident the pulse was 120 and could scarcely be felt, and the patient had become unconscious. I then injected under the skin of the abdomen two pints of artificial serum (sodium chloride), and within five minutes the pulse had returned, and gradually slowed down to 100. An hour after I again gave one pint of the serum, and consciousness returned. Eight hours after the accident the pulse was 90, and she fell asleep. The next day the pulse was normal. Evidently a large, firm clot had formed around the ruptured blood vessel, and had stopped the haemorrhage. The serum at the critical moment had helped the circulation and saved her life. She lived several years after this.

I think a correspondence on this subject from men who have had similar experiences might result in saving life that would easily be sacrificed through want of patience and perseverance on the doctor's part.—I am, etc.,

D. E. ANDERSON, M.D., B.A., B.Sc.Lond.

Obituary.

BENJAMIN MOORE, D.Sc., M.R.C.S., L.R.C.P., F.R.S.,
Professor of Biochemistry in the University of Oxford.

THE news of the premature death at the age of 55 of Professor Benjamin Moore will be received with universal regret. It occurred on March 3rd from heart failure following an attack of influenza last January. He received his early education partly at Queen's College, Belfast, and partly at University College, London, where he was a pupil of the late Sir William Ramsay, and worked for five years in the chemistry department. He was for a time teacher of physiology in the medical school of Yale College, New Haven, but returned to London to become lecturer on physiology in the medical school at Charing Cross Hospital. In 1902 he was appointed to the newly founded Johnston Chair of Biochemistry in the University of Liverpool, the first of its kind to be established in this country. He retained this appointment until 1914, and it was while occupying it that many of his most important contributions to biochemistry were published. He contributed an article on the chemistry of digestion to Schafer's *Textbook of Physiology*, and another on the energetics of cell secretion and nutrition to Hill's *Recent Advances in Biochemistry*. He was one of the founders of the *Biochemical Journal* and a frequent contributor of important articles to its pages. He was, during a time of great expansion, Dean of the Medical Faculty of the University of Liverpool, an office in which he rendered good service. He was elected F.R.S. in 1912.

In 1914 he resigned his chair in Liverpool to become a member of the staff of the Department of Applied Physiology of the Central Research Institute of the Medical Research Council. During the war much of the energy of the institute were given to problems it raised, and Moore took a leading part in investigations carried out in co-operation with the Health of Munition Workers Committee and the Factory Department of the Home Office into the action of various poisonous dusts and vapours arising in the process of munition manufacture. During 1916-17 he undertook the direction of inquiries of the utmost importance with regard to T.N.T. poisoning. The investigations included not only work in laboratories but many inquiries at different factories, in which the laboratory results were given a practical application and a variety of protective methods devised and studied. In 1918 he published the results of his work on photo-chemical syntheses; part of it, done in conjunction with Mr. T. A. Webster, was related in a paper in the *Proceedings of the Royal Society* on the action of light rays on organic compounds, and the photo-synthesis of organic from inorganic compounds in presence of inorganic colloids. At the same time he was determining some of the elementary chemical conditions necessary for the growth of algae. Later on, in conjunction with a number of colleagues, he was able to show that both

fresh water and marine algae, nannid by bacteria, were able in summer to fix nitrogen from the atmosphere, and incidentally advanced evidence to show that the so-called "active oxygen" of fresh country air is not ozone, but nitrogen peroxide, probably formed by ultra-violet light causing direct union of nitrogen and oxygen. These researches, which were continued in subsequent years, and upon which he published a number of papers, confirmed his interest in inquiries directed to ascertain the origin of life on the earth. It had, perhaps, first been aroused during his frequent visits to the Marino Biological Station at Port Erin in the Isle of Man. His latest publication was entitled *Biochemistry, a Study of the Origin, Reactions, and Equilibria of Living Matter*.

Less than two years ago he was appointed to the chair of biochemistry at Oxford, founded by Mr. Edward Whitley. In his earlier years his work was assisted by grants made by the Science Committee of the British Medical Association, and since 1917 he had been a member of that Committee and an active worker on its Subcommittee on Medical Research and Laboratory Workers. In 1912, when the annual meeting met at Liverpool, he was vice-president of the Physiological Section.

Moore gave a great deal of time, energy, and thought to the borderland of medicine and sociology. His interest in such questions and in the British Medical Association led him to accept office as representative of the Birkenhead Division; in that capacity he took an active part in the Representative Meetings in 1909-10, and again in 1910-11. He wrote much in many publications on medico-sociological subjects, and his views were summarized in a book entitled *The Dawn of the Health Age*. When the Association held its annual meeting in Cambridge in 1920 he was a vice-president of the Medical Sociology Section.

Benjamin Moore was a man of volcanic energy which found many outlets, perhaps too many, but he has left his mark upon the department of science to which he specially devoted himself—that of biochemistry.

ALFRED HILL, M.D.,

Formerly Medical Officer of Health for Birmingham.

DR. ALFRED HILL, who died on February 22nd, aged 95, at Freshwater Bay, Isle of Wight, was believed to be the oldest member of the British Medical Association, having been elected in 1853. He was born in 1826, and at the age of 16 he was articled to his uncle, Mr. Joseph Heeley, a surgeon at Stone, Staffordshire. He became a medical student at Birmingham, and took the diplomas of L.S.A. and M.R.C.S. Eng. in 1850, graduating M.D. at King's College, Aberdeen, in 1854. In 1851 he was elected to the chair of chemistry, and later to that of toxicology, at the Sydenham College Medical School and Queen's College, Birmingham. Ten years later he was appointed public analyst, and when the Public Health Act of 1872 came into force he was appointed medical officer of health of the city of Birmingham. Dr. Hill assisted in the important work of setting up a proper system of sewage disposal in Birmingham, and he was the author of many articles on subjects connected with public health. He was a former president of the Society of Public Analysts and of the Society of Medical Officers of Health, and he played a leading part in the development of the public health service in this country. He retired to the Isle of Wight in 1903, when he resigned the post of medical officer of health. His surviving sons include Dr. Bostock Hill, consulting medical officer of health for Warwickshire and emeritus professor of hygiene and public health at Birmingham University, and Dr. Eustace Hill, medical officer of health for the county of Durham and late professor of public health at Durham University.

We are indebted to Dr. JOHN C. McVAIL for the following:

The generation to which Dr. Alfred Hill belonged has passed away. No one now in the fighting line of public health can properly claim to have been his contemporary, though the later years of his work coincided with the earlier years of some men who are still in the service. It is more than seventy years since Dr. Hill became a professor of chemistry in Birmingham and half a century since he was made medical officer of health under what was then the new Public Health Act. In these far-off days the work was very different from that of the present time. Lister had gone from Glasgow to Edinburgh to continue, under the inspiration of Pasteur, the laying of the foundations of modern scientific

surgery. But for preventive medicine the era of bacteriology had not dawned and the light of entomology in relation to public health was still further below the horizon. In the absence of such guidance the new medical officers of health, of whom Dr. Alfred Hill was one of the chief, were wisely relying on the establishment and maintenance of municipal cleanliness as the mainstay of their policy. Dr. Hill, both chemist and health officer, was concerning himself with and writing on such basal subjects as water supply in large towns in relation to health, house drainage, sewage disposal—a particularly difficult problem in a large city far from the sea—and the regulation of house building. At the time when he became medical officer Europe was being swept by the great pandemic of small-pox which followed the Franco-Prussian war, and health authorities and their medical advisers were realizing more clearly than they had ever done before, excepting in Germany, the need for revaccination in supplement to primary vaccination. The importance of hospital provision for the isolation of infectious diseases was also pressing itself on public and professional attention. Compulsory notification came later, and was dealt with by Birmingham's medical officer.

I had the pleasure of meeting Dr. Hill when I presided over a conference of health officers at Birmingham close on a quarter of a century ago. His work only I had known previously. I recollect him as a handsome man, of fine presence and old-fashioned courtesy. He did a great work for the industrial capital of the Midlands, and he has enjoyed a long evening of honoured retirement after his life-duty was accomplished. He leaves behind him sons who worthily and successfully follow him in the field of disease prevention, and in the education of yet another generation of doctors in the principles and practice of hygiene and public health.

ALEXANDER STRVENSON GREENWAY, T.D., Lieut.-Col. R.A.M.C. (T.F.), died at Belvedere, Kent, on February 20th, aged 69. He was educated at Edinburgh University, where he graduated M.B. and C.M. in 1874, and M.D. in 1880; he took the M.R.C.S. in 1878. After filling the posts of house-surgeon of the Hertford British Hospital in Paris, senior resident medical officer of St. Mary's Hospital, Manchester, and house-surgeon of the county hospital at Huntingdon, he went into practice at Belvedere, Erith, Kent, where he was medical officer of the Belvedere dispensary and Erith cottage hospital; surgeon to the metropolitan police, to the post office, and to the Royal Alfred Institute for Aged Seamen, and ex-president of the Belvedere and Erith Natural History and Science Society. He had served for a long time in the auxiliary medical force, volunteer and territorial, and attained the rank of lieutenant-colonel, R.A.M.C. (T.F.), on April 1st, 1908, as commandant of the 4th London (Woolwich) Field Ambulance, which post he still held when the war began in August, 1914. He had received the Territorial Decoration.

JAMES NEAL MACMULLAN, T.D., Major R.A.M.C. (T.F.), died at Woking on February 23rd. He was educated at Queen's College, Belfast, and took the Scottish triple qualification in 1893. Before the war he was in practice at Regent's Park, London. He joined the R.A.M.C. (T.F.) as lieutenant and medical officer of the Herefordshire regiment on August 1st, 1903, became captain on November 1st, 1906, and was promoted to major on August 5th, 1914. He had received the Territorial Decoration.

THE death is announced of Dr. C. T. CAMPBELL, of London, Ontario, in his 79th year. He received his medical education at Cleveland, obtaining his licence from the Canadian Board in 1856. He was formerly a member of the Ontario Medical Council, became vice-president of the Canadian Medical Council in 1892, and president in the following year. He served for many years on the London Board of Education, of which he was chairman in 1884; he was also an alderman, and in 1905 mayor of the city. He was much interested in historical research, was first president of the local historical society, and was a contributor on historical subjects to various magazines. He was twice married, and is survived by his widow.

ACCORDING to the *Deutsche medizinische Wochenschrift*, the losses of Germany in the war were 1,838,545 dead and 4,247,143 wounded, the medical profession signing in these totals with 1,675 dead and 2,200 wounded.

Universities and Colleges.

UNIVERSITY OF MANCHESTER.

Dr. H. R. DEAN, as announced last week, has been appointed professor of bacteriology at University College Hospital Medical School, London, and has in consequence resigned the Proctor chair of pathology and pathological anatomy. The Council, in accepting the resignation with much regret, expressed to Professor Dean their cordial thanks for the valuable services he has rendered to the University during the last seven years in teaching, in research, and, in particular, in the reconstruction of the department of pathology. They offered their congratulations to Professor Dean on the important post to which he has been appointed, and wished him all success and happiness.

The Council also expressed congratulation to the following on their recommendation for election as Fellows of the Royal Society: Professor F. L. Pyman, formerly a student, and at present professor of technological chemistry in the University; Professor D. M. S. Watson, formerly a student, and later a member of the staff of the University; Mr. C. G. Darwin, formerly a member of the staff of the University.

The Services.

TUBERCULOUS OFFICERS AND NURSES.

THE Ministry of Pensions announces that officers and nurses suffering from pulmonary tuberculosis accepted by the Ministry as attributable to or aggravated by service in the great war will, under certain conditions, receive retired pay or pensions at special rates for certain periods:

1. Officers and nurses who have completed a course of sanatorium treatment, and who are certified as likely to benefit by a further course of extended treatment combined with training will, if they decide to undergo such a course, continue to receive retired pay or pension at the rate for the highest degree of disablement (100 per cent.) from the commencement of the course until its termination. After the further course has terminated they are entitled without further medical examination by a Ministry Board to retired pay at the rate of 100 per cent. for a period of six months, and at the minimum rate of 50 per cent. for two years thereafter. These awards, which may cover a period of two and a half years in all, are subject to the condition that the officers present themselves for examination by a tuberculosis officer from time to time as directed. The concession applies only to officers and nurses certified as likely to benefit by the further course referred to, and agreeing to undergo and undergoing such a course.

2. Officers and nurses who are discharged from sanatoriums on or after December 22nd, 1921, will be granted retired pay or pension at the special rate of 100 per cent. for a period of six months after leaving the institution, provided that the course of treatment was satisfactorily completed, and that the pecuniary circumstances of the officer or nurse are such that worry and uncertainty which might be prejudicial to health would result if the special rates were not granted. The grant will not be retrospective before December 22nd, 1921. At the end of the six months period an award will be made at the rate of not less than 50 per cent. for a further two years, subject to the same conditions, and provided that the officer or nurse continues to comply with the medical requirements of the Ministry.

DEATHS IN THE SERVICES.

Lieut.-Colonel Frederick Rowland Barker, M.B.E., R.A.M.C. (retired), died at Worthing on January 22nd, aged 68. He was born at Stoke-on-Trent on March 18th, 1853, and received his medical education at St. ... He took the M.R.C.S. in 1877, the L.S.A. in ... in 1879, and the D.P.H. Cantab. in 1887. He served as surgeon to the Red Cross Society in the Turko-Serbian war of 1876-77, receiving the fifth class of the Medjidie, and as surgeon to the Stafford House Committee in the Russo-Turkish war of 1877-78, receiving the Turkish war medal and the fourth class of the Order of the Osmanli. At that time the terms of service in the Army Medical Department were not considered satisfactory by the profession, and finding it impossible to obtain medical officers of good qualifications on the old terms, the War Office found it necessary to offer much better terms of service. The first competitive examination held under the new and improved terms took place in the latter part of 1879, the selected candidates being commissioned after their Netley training from March 6th, 1880. There was a great rush of candidates for commissions under the new terms, and at the examination Barker headed the list of successful candidates, the second place being taken by one who was destined to go much further, Sir Alfred Keogh. Barker became lieutenant-colonel on March 6th, 1900, and retired on September 15th, 1900. He served in the South African war in 1893-1920, receiving the Queen's medal with three clasps.

Major Walter Tibbits, R.A.M.C. (retired), was killed by a fall from a train near Stowmarket on January 15th. He was born at Warwick on March 25th, 1870, and educated at Edinburgh, where he graduated M.B. and C.M. in 1892, and at the Middlesex Hospital. Entering the army as surgeon-lieutenant on January 29th, 1894, he became major on October 29th, 1905, but was not further promoted, and retired after the war was over, on February 1st, 1920. He was still employed, however, after retirement in medical charge of the dépôt at Ipswich. He served with No. 1 General Hospital in the Tirah campaign on the North-West frontier of India in 1897-98, and in the South African war in 1901-02, receiving the Queen's medal with two clasps.

Captain Andrew Cooper Cassells, late South African Medical Corps, died at Maritzburg, South Africa, on December 18th, after a long illness. He was the fourth son of James Cassells, of Leven, and was educated at Dundee and St. Andrews, where he graduated as M.B. and Ch.B. in 1915, after which he took a commission as lieutenant in the Special Reserve of the R.A.M.C., subsequently being transferred to the S.A.M.C.

Medical News.

THE forty-fourth annual meeting and St. Patrick's Day dinner of the Irish Medical Schools' and Graduates' Association will be held, on March 16th, at Pagan's Restaurant, Great Portland Street, when Major-General Wallace Kenny, C.B., will resign the presidency to Dr. J. A. Macdonald, who will take the chair. The Right Hon. Edward Shortt, Home Secretary, will be the special guest at the dinner, on which occasion the Arnett gold medal of the association will be presented to Lieut.-Colonel Robert McCarrison, I.M.S., M.D., LL.D. Tickets (9s. each) may be obtained for the dinner from Dr. F. Howard Humphris, 8, West Chapel Street, W.1.

AT a meeting of the Manchester Clinical Society, to be held in the physiological theatre of the University of Manchester on Thursday, March 16th, at 4.30 p.m., Professor Leonard Hill will give an address on the physiological principles underlying light treatment and heliotherapy; all medical practitioners are cordially invited.

WE are asked to state that hospitals in the county of London, or within nine miles of Charing Cross, desiring to participate in the grants made by the King Edward's Hospital Fund for London for the year 1922, must make application before March 31st to the Honorary Secretaries, 7, Walbrook, E.C.4. Applications will also be considered from convalescent homes which are situated within the above boundaries, or which, being situated outside, take a large proportion of patients from London.

A DEPUTATION, organized by the Catholic Women's League, waited recently upon the Minister of Health to protest against the active propaganda carried on by individuals and certain public bodies regarding birth control. The deputation asked as ratepayers that advice or lectures on the subject should not be given in the maternity and child welfare centres which received grants from the Ministry of Health. The deputation was sympathetically received by Sir Alfred Mond.

A POST-GRADUATE course dealing with recent ideas in medicine and surgery on diseases of the liver, bile ducts, and pancreas, and on diabetes will be held at the Hôtel Dieu, Paris, commencing on April 10th, and continuing for two weeks. The instruction will take a practical form, and will be carried out under the direction of Dr. Maurice Villaret, with the collaboration of M. Okinczye and others. The fee is 150 francs, and further information may be had from the secretary of the Faculty of Medicine, Paris.

CAPTAIN STEWART RANKEN DOUGLAS, I.M.S. (ret.), Director of the Department of Bacteriology, Protistology, and Experimental Pathology at the National Institute for Medical Research, is among the fifteen candidates selected by the council of the Royal Society for election into the society.

THE proceedings on the conference on lunacy administration in London on January 19th and 20th, under the presidency of Sir Frederick Willis, chairman of the Board of Control, were reported in our issue of January 28th. An official verbatim report has now been issued by the Stationery Office, and can be purchased through any bookseller, price 2s. 6d.

ALTHOUGH the City of New York has been experiencing an outbreak of pneumonia and influenza, the bulletin issued by the Health Department on February 2nd appears to show that down to that date there had been no unusual prevalence of these diseases in the State of New York. In spite of the recommendation of vaccines for the prevention of pneumonia by the New York City health commissioner the State Health Department does not favor their use, the report indicating that during the last epidemic little or no protection against pneumonia appeared to be afforded by the use of vaccines.

A RESOLUTION that dogs should be exempted from scientific experimentation was put before the New York City Federation of Women's Clubs at its annual convention, but was defeated by an overwhelming vote.

A NEW radium institute has recently been opened at Naples with much ceremony and a banquet; its foundation is due to the initiative of Dr. R. Stanziale, professor of dermatology and syphilis.

AN additional telephone exchange was opened within the boundaries of the City of London on March 4th. The new "Bishopsgate" exchange is intended to serve an area embracing the thoroughfare of that name and extending to Whitechapel, Bethnal Green, and Haggerston. As it is situated within five miles of Oxford Circus, the central telephone measuring point, calls may be passed for 1½d. up to a distance of ten miles from Oxford Circus.

THE International Committee set up by the International Labour Office of the League of Nations to consider problems of war disablement met in Geneva on March 2nd. The British representative on the Committee is Major J. B. Cohen, M.P.; the Health Section of the League of Nations, the Red Cross Organizations, and the Inter-Allied Committee of Disabled Men are also represented. The subjects for discussion include the holding of an international exhibition to show the progress made in the manufacture and use of artificial limbs, and the administrative organization of prosthesis and orthopedy. A comparative study of the existing arrangements in the various countries and the results obtained will be undertaken, and the future of the organization for the supply of limbs will be discussed. The third question before the meeting is the organization of medical treatment for disabled men. This will also be dealt with by a comparative study of the existing national systems, and the Committee will be invited to discuss the methods by which men disabled in industry may receive the same benefits as men disabled in the war. Special consideration will be given to the position of disabled men who live abroad, and may therefore be unable to obtain prosthesis and medical treatment. Some States have concluded reciprocal agreements in order to deal with cases of this kind. The Committee will consider the possibility of promoting the wider adoption of such agreements, and the practicability of securing an international convention laying down fundamental principles for the international protection of men disabled in the war.

DR. C. A. MOORE, on the occasion of his retirement from the post of medical officer to the Leicester Post Office after thirty years' service, has been presented by the various staffs with an electro-plated breakfast dish, gold cuff-links and studs, and a case of pipes and a pouch, as a mark of their appreciation for his courteous attention to them during his term of office.

AT the January matriculation examination of the University of London there were 101 successful candidates in the first division and 984 in the second division; the supplementary certificate in Latin was granted to 50 candidates.

THE number of prescriptions for alcoholic liquor issued in Ontario during December, 1921, was 71,028; 311 medical practitioners were suspended by the Board of License Commissioners for exceeding their monthly quota of fifty prescriptions.

AT Durham assizes, on March 3rd, Mr. Justice Bray passed sentence of twelve months' imprisonment in the second division upon Edward Ernest Willis, aged 50, a registered medical practitioner, who was found guilty of the manslaughter of the wife of a miner at New Herrington on October 13th, 1921. The prosecution alleged that in operating on the deceased woman Dr. Willis did not use reasonable skill and care, and was guilty of criminal negligence. Evidence was given that he attempted to perform an obstetrical operation while under the influence of drink, and fatal internal injuries were inflicted upon the patient. The accused held the salaried post of medical officer to the Newhottle Miners' Medical Club.

THE late Mr. E. J. Maher-Smith has bequeathed £2,000 to the Swansea General and Eye Hospital and £1,000 to Gny's Hospital. In addition Swansea Hospital receives one-fourth and Gny's Hospital one-eighth of the residual estate.

AT the meeting of the Society of Public Analysts, on March 1st, Mr. Raymond V. Wadsworth reported that the analyses of cocoa beans from twenty-one different areas showed a variation in the theobromine content of the nib from 2.2 per cent. to 3.9 per cent., calculated on the dry fat-free material. The variation was due, first, to the variety of the bean, the Criollo bean containing much less theobromine than the Forester, and, secondly, to the amount of fermentation, for by it the theobromine was considerably reduced. In the shell the theobromine varied much more. During the process of fermentation the alkaloid is brought by the sweatings from the nib to the shell, and the amount naturally present in the shell, 0.19 per cent., might thus be increased to 2.89 per cent. During roasting there was practically no loss of theobromine from either nib or shell. The analyses of twenty-two brands of commercial cocoas showed a variation in the theobromine content of 2.39 per cent. to 3.55 per cent., calculated on the dry fat-free cocoa.

AT a special council meeting of King Edward's Hospital Fund for London, held on March 8th, the main lines of a contributory scheme for the London hospitals and a combined public appeal were approved.

THE number of deaths from influenza during the week ending March 4th continued to show a decline. In the 105 great towns it was 395, against 525 in the previous week; in London it was 43, against 77.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aitiology*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2620, Gerrard.
3. MEDICAL SECRETARY, *Medisecra*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus*, Dublin; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate*, Edinburgh; telephone, 4361, Central).

QUERIES AND ANSWERS.

B." would be glad of advice as to the best treatment for oken chilblains of a very painful nature on the toes of a farmer aged 65 years.

VITAMINS.

R. H."—Vitamins are not destroyed by freezing or refrigeration. The rate of destruction of vitamins depends more upon the length of time to which they are exposed to oxygen than upon the temperature. If exposed to oxygen vitamins are slowly destroyed, even when kept at freezing point. They are destroyed so rapidly at low temperatures than at high temperatures. The optimum conditions for preserving vitamins appear to be: (1) absence of oxygen; (2) neutral or feebly acid reaction; (3) dry condition (rather than in solution); (4) low temperature.

TESTICULAR NEURALGIA.

DR. M. W. BROWDY (London) writes: In reply to "E." (p. 374), I would advise him to have a urethroscopic examination made of the posterior urethra, as I have seen a good many cases in which the neurosis arises from chronic disease of the colliculus seminalis. In these cases excision of the testicles would be a calamity.

INCOME TAX.

"D. K." bought a practice for £2,800, paid £1,000 down, and is paying the remainder by instalments of £600 per annum.

* * * He can claim no allowance for the payments, which are of a capital nature.

"COTSWOLD" is paying premium for a deferred annuity becoming payable in 1924 for four years. He asks if he can claim an allowance.

* * * Since 1916 payments to life assurance companies are not proper subjects for claim unless the benefit is a capital sum payable on death. In this case no allowance seems to be due.

"VENATOR" asks what deductions can be claimed as living expenses by an outdoor assistant?

* * * There is no ground for claim in respect of living expenses; an "indoor assistant" who receives a portion of his total remuneration in kind—and therefore in a form rendering it unassessable to income tax—is in a peculiarly favourable position as compared with other persons whether assistants or practitioners.

"W. R." inquires as to the deduction of certain expenses.

* * * (1) The fraction of general expenses, such as rent, light, etc., varies with the locality; in a provincial town a common proportion is one-half. (2) The amount to be allowed for domestic staff is the sum—whether expended as wages or in "keep"—applicable to that portion of the total service which is employed in cleaning the waiting- and consulting-rooms and similar professional matters. If the whole of the cost of a maid is allowed "W. R." is not likely to obtain more. (3) Nothing is allowable for depreciation of a car used in professional work, but the cost of replacement can be deducted as and when incurred.

LETTERS, NOTES, ETC.

THE TREATMENT OF PNEUMONIA.

DR. H. L. GORDON (Aecrington) writes: May I suggest to anyone not satisfied with his own treatment of this dread disease the following: R Pot. iod. 5j, liq. ammon. acet. conc. 5ij, aq. ad 5viij. 3ss. every two hours. As pneumococcal invasion increases blood pressure, the indication is to lower it. This I claim as the rationale of the treatment suggested. I am satisfied with it, but it must be begun as soon as the nature of the case is suspected and not as a last resource.

DR. ARTHUR J. MATHISON (Hornsey) writes: In the JOURNAL of February 25th, on p. 334, "M.D." writes on the treatment of pneumonia. It is necessary always to remember the great difference between lobar and lobular pneumonia—a difference better set forth in those other names, *roupous* and *catarrhal*. It is also necessary to remember that the lobular pneumonia, generalized, closely resembles the other form, giving a large area of solid lung so far as percussion and auscultation discover. The dispute into which creosote may have fallen is probably due to this mistake. I do not put forward the creosote and potassium iodide treatment as a specific in lobular, but only in lobar pneumonia. During the epidemic of influenza in 1918-19 I found cases that would not yield to the treatment, and I hastily doubled the dose and wrote to the JOURNAL to that effect. But now I see that those cases were probably either (a) cases of mixed infection, or (b) cases of lobular pneumonia, or both (a) and (b). The mixture should stand as used with so much success. Every four hours till the temperature falls give 2½ minims of creosote and 5 grains of potassium iodide. The mixture should only be expected to act as a specific in lobar pneumonia and never in cases with failing heart, in which cases the heart would be still further depressed by a mixture unsuitable at so late a stage. Surely to be a specific for so widespread and fatal a disease as lobar pneumonia is quite distinction enough for this simple combination of drugs without adding the very doubtful reputation it might earn in the other very different malady. Brandy is not as a rule necessary.

AMMONIUM CHLORIDE IN GLYCOSURIA.

DR. T. HOUGHTON MITCHELL (Ambleside, Westmorland) writes: May I draw the attention of readers to the efficiency of ammonium chloride in glycosuria of hepatic origin? Given in full doses three times a day before meals, combined with *tanxagum*, compound spirits of ammonia, and *nux vomica*, it speedily reduces the sugar content and produces a rapid fall in the specific gravity of the urine.

DEPILATORIES.

WITH reference to our note on depilatories (February 11th, 1922, p. 252), a correspondent writes that the advice to use a safety razor in cases of unwanted growth of hair is often met by the objection that the constant shaving will cause the hair to come more quickly and of stronger growth. He asks if there is any ground for this apprehension, and whether this objection does not apply also to the use of barium paste on account of the irritation which it causes. Constant shaving does appear to cause the hair to grow more strongly, but the only real objection to shaving seems to be that it has to be done at frequent intervals in any case.

GIGANTISM.

DR. H. E. BLOXSONE (Fairford, Gloucestershire) writes: A girl was brought to me recently as her rate of growth was causing some alarm. I could not find anything abnormal except her size. She is 14 years old, 6 ft. high, and weighs 15 st. She is immensely broad and deep in the chest and perfectly well-proportioned everywhere. She is rather fat, but the weight is as much bone as fat. She is quite intelligent. The mother and father are ordinary healthy, medium-sized people, but the daughter is surely a giantess.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 34, 35, 37, 38, 39, and 40 of our advertisement columns, and advertisements as to partnerships, assistantships, and locum tenencies at pages 35 and 37.

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *poste restante* letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

227. Diagnosis of Cancer of the Lung.

CREYX (*Journ. de méd. de Bordeaux*, December 10th, 1921), who reports two cases in which primary cancer of the lung was not discovered till the autopsy, remarks that, though the diagnosis of secondary cancer of the lung is sometimes wrongly made, errors are much more frequently committed in regard to primary cancer of the lung, as might be expected from the extreme rarity of the condition. All writers are now agreed that there are no symptoms or physical signs peculiar to primary or secondary cancer of the lung. Sometimes the symptoms are entirely misleading and suggest heart disease, as in Demange's case, in which there was a murmur of tricuspid insufficiency due to thrombosis of the pulmonary artery, or in the case of Spillmann and Hanshalter, in which a diastolic murmur at the base, due to compression of the root of the heart, and the pallor of the face suggested aortic insufficiency. Bocage found that pericarditis with effusion was simulated on several occasions. Creyx points out that the persistence of signs of induration regarded by Stokes as characteristic of cancer of the lung may occur in all cases of sclerosis of any extent, even of a tuberculous nature. Rapid reaccumulation of pleural fluid after puncture is also far from possessing the diagnostic value attributed to it, as it is sometimes met with in tuberculous pleurisy in which an effusion may last for weeks and even months. The prune juice expectoration, also regarded by Stokes as a valuable sign of cancer of the lung, only occurs when ulceration has taken place. The presence of particles of the new growth in the sputum, which is the only sure sign, is excessively rare, as is shown by the fact that Kurt Wolff did not find a single example of cancer cells in the sputum among 31 cases of cancer of the lung. X rays also do not clear up the diagnosis, except, perhaps, in the cases where the lung parenchyma is infiltrated with neoplastic growths (almost always of secondary nature), which are sharply separated from one another by extensive areas of healthy tissue.

223. Complications of Rubella.

BÉNARD (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, November 10th, 1921), during an epidemic of 291 cases of rubella at the Versailles military hospital from February 20th to June 20th, 1921, saw 13 cases, or 4.5 per cent., with meningeal complications. These appeared between the sixth and eighth days and might assume various forms, which were classified as follows:—
 1. Intermittent, meningeal.
 2. As a rule they ran a mild course and even fatal.
 3. As a rule they ran a mild course and even fatal.
 Bénard reports a fatal case in which symptoms of Landry's paralysis developed on the fourth day of a typical attack of rubella, death taking place three days later. Commenting on Bénard's communication, Florand and Ficssinger (*ibid.*, November 17th, 1921) report a case showing that rubella may have similar complications to those of scarlet fever. The patient was a previously healthy soldier, aged 21, who six days after a typical attack of rubella developed a mild streptococcal septicaemia with endopericarditis and subcutaneous abscesses. The patient was on the high road to recovery when he was last seen.

229. Nonne's Four Reactions in Syphilis.

GOEDHART (*Nederl. Tijdschr. v. Geneesk.*, October 29th, 1921) has investigated Nonne's four reactions (Wassermann reaction in the blood and cerebro-spinal fluid, Nonne's reaction, and lymphocytosis) in 83 cases of syphilis; 18 of these cases had more or less severe involvement of the central nervous system and the remaining 70 were all examples of old-standing or latent syphilis. In 51 of the 70 cases the cerebro-spinal fluid was entirely normal, and in 19 showed the following changes: Nonne's reaction was positive in 17, being present alone in 10 cases and in association with lymphocytosis in 7 cases. In 2 cases lymphocytosis alone was present, the Wassermann reaction was feebly positive in 5 cases, but was always associated with one of the other reactions. Of the 18 cases in which nervous symptoms were present 9 had not received any antisyphilitic treatment, and in the others the treatment had been very incomplete. Nonne's reaction was positive in all, lymphocytosis was absent in 6 and present in the rest. The Wassermann reaction was negative in the blood in 4 cases and in the cerebro-spinal fluid in 8.

230. Complications of Salvarsan Treatment.

ARCHAMBAULT (*Paris méd.*, November 26th, 1921) remarks that the present tendency is to divide the accidents due to salvarsan treatment into two groups. The first consists of toxic complications due to oxidation of the drug, which were more frequent with "605" than with "914," which is a more stable product. The symptoms in this group appear late, and consist of nervous manifestations, and especially paresis of the lower limbs. In the second group the symptoms are those of protein shock and haemoclastic or nitritoid crises, being due to precipitation and flocculation of the serum. Experimental guinea-pigs show pulmonary embolism and sometimes infarction, and the intestinal mucous membrane presents a haemorrhagic stippling. These symptoms appear early, and are often fatal. It appears that certain products give rise to them more frequently than others. Out of 800 intravenous injections performed by Archambault on forty-eight patients in the course of a year only four presented really serious symptoms. In three there was a nitritoid crisis, and one had an almost fatal icterus. All had been treated by Ravaut's method, the patient being in a recumbent position and the injection carried out slowly. The doses were rarely as much as 0.90 or 1.05 gram.

231. The Teeth and Congenital Syphilis.

KRANZ (*Zentralbl. f. inn. Med.*, December 24th, 1921), as the result of ten years' study of dental anomalies in dental practice, maintains, in opposition to E. and M. Kraupa, that the so-called Hutchinson's teeth are by no means always a typical sign of congenital syphilis. He has found them in undoubtedly non-syphilitic individuals, and especially in cretins. They are, moreover, relatively uncommon, and Hutchinson himself stated that he regarded them as a sure sign of syphilis only when they formed part of his triad. Kranz also maintains that all disturbances of growth in the period of development, including changes in the teeth and jaws, have a common cause, for which local mechanical influences, or the action of spirochaetes or other organisms, or nutritional disturbances are not alone responsible, the chief factor being disturbance of calcium metabolism which originates in endocrine disturbances. Owing to the relatively frequent involvement of the ductless glands in congenital syphilis dental and maxillary anomalies may be frequently found in these patients, but anomalies of shape and position are by no means characteristic of congenital syphilis.

232. Treatment and Pathology of Asthma.

BROWN (*Edinburgh Med. Journ.*, February, 1922), reviewing the research work upon the nuclei and functions of the vagus, points out that one important function of the vagus is to regulate, by its afferent impulses, the depth of respiration, thereby saving the lung from overdistension, while the respiratory centre has both an inhibitory and excitatory function regulated by the receptors in the lung, inflation and deflation of the alveoli producing inhibitory and excitatory effects upon the centre. This vagal regulation of the depth of respiration is important in asthma, the vagus acting powerfully by its afferent impulses, while it acts abnormally as regards its efferent fibres. The smooth musculature of the bronchi is under vagus control, and bronchial contraction to one-half or one-third of the previous diameter has been shown to occur when the vagus is stimulated. Under anaesthesia with ether and chloroform, however, there is a reversal of this action, stimulation of the vagus then being followed by relaxation of the muscles and dilatation of the bronchi. Spasmodic narrowing of the bronchi may be brought about reflexly, the receptors from which such reflex takes origin being in the mucous membrane of the respiratory tract, stimuli passing up the afferent vagal fibres to be reflected down the efferent. Lesions in the nostrils, chronic bronchitis, inhalation of dust or irritant gases may thus act reflexly and cause bronchial spasm. The majority of asthmatic cases result from anaphylaxis, it being sometimes possible by the skin reaction to discover the exact antigen responsible, and, when this is possible, a process of desensitization should be attempted by giving gradually increasing minute doses of the protein in question. The bronchial spasm may be arrested (1) by obtaining the reversal effect produced by inhalations of ether or chloroform, or by alcohol, all obviously dangerous when habitually used; (2) by paralysing the vagal endings in the smooth muscle by atropine or stramonium, and so causing the bronchi to dilate; and (3) by inhibiting the smooth muscle and so causing relaxation, by the administration of 1 in 1,000

solution of adrenaline. It is probable that the benefit arising from the prolonged administration of potassium iodide may be similarly explained, the iodine stimulating the thyroid and in turn increasing the suprarenal secretion.

233. The Diagnosis of Uraemic Conditions.

BETH (*Wien. Arch. f. inn. Med.*, November 15th, 1921) states that uraemic manifestations may arise under two conditions—namely, in the terminal stage of chronic nephritis and in malignant nephro-sclerosis. The two conditions resemble each other so closely in their clinical symptoms that a differential diagnosis is often very difficult. In the cases examined by Beth in which the diagnosis was confirmed by *post-mortem* findings and histological examination of the kidneys, striking differences were found in the bilirubin content of the serum and in the excretion of urobilinogen. Beth regards this difference as a means of distinguishing between the two conditions. In malignant nephro-sclerosis the bilirubin content of the serum and the excretion of urobilinogen in the urine are normal, whereas in chronic nephritis they are pathological. The cause of this is probably to be found in anaemia of an aplastic type, and also in an insufficiency of Kupffer's stellate cells.

234. The Optimum Dose of Tuberculin.

TERASSE (*Le Scalpel*, October 22nd, 1921) points out that each tuberculous patient reacts differently to tuberculin, and the object of treatment is to find the best dose for each case. He says this can be ascertained by watching the temperature chart, the local skin reaction, and the condition of the sputa. His practice is to begin with slowly increasing doses and stop whenever the temperature rises (excluding any inflammatory cause). In some cases marked and steady improvement occurs, and then, without any apparent reason and without any temperature warning, the patient remains at a standstill; in many of these cases, if the local skin reaction is observed, some oedema is noted, and this is a sign that the tuberculin should be reduced in amount. The author refers to the many discordant views as to how tuberculin acts, but in his paper he is chiefly concerned with the best dosage and the rules which should guide us in determining what is the best dose.

SURGERY.

235. Acute Haemorrhagic Pancreatitis.

SCHWARTZ (*Bull. et Mém. Soc. de Chir. de Paris*, January 17th, 1922), discussing the etiology of this condition, describes a case upon which, after operation, an autopsy was made. The pre-operative diagnosis was torsion of an ovarian cyst or rupture of a gastric ulcer, but after laparotomy the presence of blood-stained fluid in the abdomen, fat necrosis, and the fact that the pancreas was enlarged and very hard, made the diagnosis evident. At the necropsy he found gall stones in the gall bladder and bile ducts and two large ones in the pancreatic portion of the duct. The pancreas was inflamed, hard, and swollen, but there were no calculi in its ducts. Histological examination of the pancreas showed areas of complete necrosis separated by portions where the tissues were healthy, but where the pancreatic ducts showed inflammatory changes these were clearly in the smaller ducts. He considers gall stones to be the most frequent cause of acute pancreatitis, and most of the observations put forward favour this etiology. The condition is a very grave one, which, though it may resolve spontaneously, none the less demands immediate operative treatment. The operation should consist in free drainage of the pancreas and a rapid exploration of the biliary ducts. This exploration is made to discover the presence of gall stones, the cause of the pancreatitis, and will allow, once recovery has taken place, proper treatment to prevent relapse—namely, drainage of the bile ducts. All these observations have been confirmed, and in his patient there was a clear history of gall stones which was proved at the autopsy. The condition was undoubtedly due to gall stones and the histological examination showed its starting point was probably around the smaller ducts.

236. JACOBOWICI (*Bull. et Mém. Soc. Méd. des Hôpitaux de Bucarest*, September 28th, 1921) describes two cases of acute pancreatitis which are of interest owing to the rarity of the condition and the difficulty in making a correct diagnosis. The prognosis of this disease depends on its diagnosis, for the treatment is entirely surgical, and recovery depends on the time when operation is performed. Körte has shown that recovery is all the more probable when operation is carried out early, as thereby complete destruction of the pancreas and other organs is prevented. This condition is met with in

obese subjects, and particularly in those affected with gall stones. The disease starts acutely with violent pain, localized at first in the upper part of the abdomen. Other important signs are complete obstruction, meteorism, hyperaesthesia, and muscular rigidity in the supraumbilical region. The temperature is normal or subnormal, and the blood shows a leucocytosis. Gray Turner and Meyer have described a sign they consider pathognomonic—namely, bluish patches resembling *post-mortem* stains—which they observed in two cases around the umbilicus and in another in the lumbar region. Jacobowici has not found these present in his cases. Radulesco noticed that the skin of the abdomen showed a harshness and marked loss of elasticity. As a rule the diagnosis should be easy to make. The treatment adopted—namely, drainage of the pancreas—is that which is recommended by most surgeons in cases where the bile ducts are not blocked and the state of the patient does not allow a lengthy operation, leaving to a later date the treatment of the gall bladder condition. Some surgeons advise that in acute pancreatitis drainage of the bile ducts is necessary, perhaps also cholecystostomy with drainage of the common duct. Cholecystostomy is preferable to cholecystectomy, for when there is obstruction of the common duct, due to a sclerosing pancreatitis, a permanent biliary fistula would remain after a cholecystectomy, whilst a cholecystostomy allows a cholecysto-gastrostomy or a cholecysto-enterostomy to be carried out later.

237. Treatment of Appendicitis.

COLLIN (*Ugeskrift for Læger*, January 19th, 1922), who has observed about 500 cases of appendicitis at his hospital in a two-year period, publishes numerous figures with a view to throwing light on the respective merits of two principles. His predecessor, Professor Tscherning, did not consider the mere diagnosis of appendicitis sufficient warrant for immediate operative treatment; there had to be certain other well defined indications. The author, on the other hand, treated the diagnosis of appendicitis as an inevitable indication for immediate operation. Among 320 appendicectomies for acute appendicitis he had 20 deaths, and the operation mortality, classified according as the patient was operated on during the first, second, or third day of the disease, was 2, 5, and 20 per cent. respectively. In 12 of these 20 fatal cases the diagnosis of appendicitis had, indeed, been made early, but the physician in charge had temporized with opium and compresses. Analysing the last 25 deaths from appendicitis among patients under Professor Tscherning's care, the author found that in 5 the operation was deferred for more than twenty-four hours after the diagnosis had been made; 4 others died without any operation having been attempted. Another index to the unwisdom of deferring operative treatment is found by the author in the percentage of cases requiring drainage after operation. This had to be undertaken in only 12 of his 105 appendicectomies performed within the first twenty-four hours of the onset of symptoms. Thus, while only 12 per cent. of the cases operated on within the first twenty-four hours required drainage, this percentage rose to 42 for the cases operated on during the second day, and to 76 for the patients operated on during the third day.

238. Operations on the Thyroid Gland.

CRILE and LOWER (*Annals of Surgery*, January, 1922) indicate the special points in the technique of thyroidectomy. The amount of gland to be left varies with the type of goitre, and should in general be the functional equivalent of the normal gland. This would mean only a small portion of an exophthalmic gland; but in a colloid goitre a bulk larger than the normal thyroid is required, because this type is not so active as the normal gland. To obtain satisfactory exposure of the gland a transverse incision of the preglanglular muscles is often required, a median incision not allowing sufficient exposure. To tie the arteries outside the capsule they made a bloodless sharp knife separation of the true capsule from the surrounding tissues, whereby the parathyroids and recurrent laryngeal nerve were left safe. Occasionally hoarseness resulted, due to involvement of the nerve in the new scar tissue. In turning out the lower pole of the gland with the finger there is danger of traction on the recurrent nerve; or, again, a large vein may be stretched or torn, and a stream of venous blood blocks the operation field. The best method to avoid this is by grasping each vessel in advance of rupture and the primary separation of the upper attachment of the lobe so that the gland rises with but slight pull from above, not push from below. Respiratory obstruction may arise during operation, and a tracheotomy should be done early rather than late; the wound in the trachea can be closed as soon as the obstruction is removed. Inhaled blood, if the trachea be opened, is likely to cause death from bronchopneumonia, and this must be avoided by haemostasis and skilled assistance. By bearing these precautions in

mind mishaps are rarely seen. In any serious case the wound is left wide open and dressed with flanne gauze. This shortens the time of operation and prevents the absorption of wound secretion. These wounds can be closed later, as soon as it seems safe, without removing the patient from bed. If there is any doubt as to the outcome during operation, it should be stopped and the wound left widely open. Patients are not deceived as to the time of operation. If they demand to know they are told. If the condition then becomes unsatisfactory operation is deferred. X-ray treatment has the following disadvantages: (1) the dose required to produce an effect is at best a guess; (2) relapses are common; (3) delay in failure leads to serious damage to certain organs—myocardium, nervous system, and liver; (4) in operation later, scar tissue and adhesions are a handicap. The diagnosis of hyperthyroidism is the indication for thyroidectomy, and the mortality is almost as low as that of appendicectomy. They advise the rule—operate on diagnosis.

239. Chronic Intestinal Stasis.

PAUCHET (*Arch. méd. belg.*, September, 1921) states that Laue's disease, or chronic intestinal stasis, is a remarkably frequent condition. A large number of cases of nervous disease, arthritis, and migraine are due to this cause. Numerous morbid processes, including tuberculosis, cancer, and rheumatism are aggravated by it, and many acute diseases are only grave or fatal because they develop in persons who are the subjects of chronic intestinal stasis. The cause of the disease is habitual constipation, which is the consequence of a slight congenital narrowing of the rectum as the result of a band or haemorrhoids, or of bad habits developed in childhood. Chronic intestinal stasis, however, is not synonymous with habitual constipation. In most constipated subjects the stasis is situated in the rectum or sigmoid, and does not give rise to symptoms of absorption. In Laue's disease, on the other hand, the delay in transit occurs higher up, such as the last part of the ileum, the caecum, or ascending colon. The faeces, which are still fluid in these situations, are easily absorbed, and symptoms of chronic toxæmia develop. Chronic intestinal stasis is the result either of atony and elongation of the large intestine or of kinks due to visceropexis, and a fibrous reaction of the peritoneum, which gives rise to thickened suspensory ligaments by which the intestine is partially strangulated. The kinks are usually situated in the following positions: (a) The duodeno-jejunal angle; (b) the termination of the ileum; (c) the hepatic and splenic flexures of the colon; (d) the union of the rectum and sigmoid with the descending colon. The effects of chronic intestinal stasis are observed on the liver, the thyroid and other glands of internal secretion, the breasts, pancreas, ovaries, and the nervous, digestive, circulatory, respiratory, and muscular systems. The condition is usually not recognized, but is mistaken for enteropexis, chronic appendicitis, enteritis, intestinal tuberculosis, gastric and duodenal ulcer, movable kidney, cholecystitis, neurasthenia, hysteria, etc. The diagnosis is made by finding the barium meal still present in the caecum ten to twelve hours after its administration, or in the caecum and colon after twenty-four to thirty-six hours. If the stasis is pronounced and symptoms of intolerance are marked, operation should be performed at once; but Pauchet is convinced that there may be an initial period of several years during which the disease remains purely functional, the symptoms being due to insufficiency of the glands of internal secretion, especially the thyroid. In such cases treatment by glandular extracts is indicated. Evacuation of the bowels should be facilitated by the administration of paraffin, and the general health improved by physical culture, massage, air, and light. On the other hand, the earlier operation, such as caeco-sigmoidostomy or colectomy, is done, and the younger the subject, the better are the results.

240. The Treatment of Tuberculous Spondylitis.

DALLA VEDOVA (*Stadium*, January 20th, 1922), speaking at the recent orthopaedic congress, said that in view of the mechanical importance of the spinal column, mechanical support of the spine is essential in spinal disease. The general health should be maintained in as good a condition as possible so as to offer adequate resistance to any infective processes. Complete rest is essential. Immobilization can be obtained by various mechanical supports, but none are so good as bony ankylosis of the arches and apophyses. This can be accomplished by osteoplastic operations. Of the various methods used, that first devised by Albee still remains the most efficacious. It can be used at all ages and in all phases or sites of the disease, but is contraindicated in septic conditions, or where definite paralysis is present, or where a multiplicity of lesions or visceral complications have reduced the patient to a low condition. The slighter and more localized the lesion, the better the result.

OBSTETRICS AND GYNAECOLOGY.

241. Myomata Complicating Pregnancy, Labour, and the Puerperium.

BALFOUR MARSHALL (*Glasgow Med. Journ.*, February, 1922), in considering myomata as a complication of pregnancy, distinguishes between cases which may be safely allowed to progress to term, those requiring operation but suitable for myomeotomy, and, lastly, those requiring hysterectomy. It is doubtful, he remarks, if artificial induction of abortion is ever justified for uncomplicated myomata alone, and owing to the improved prognosis of Caesarean section at the present day it is safe to leave till the end of pregnancy myomata which will prevent the birth of a full-time living child. Partly owing to accelerated growth, but chiefly to oedema, myomata increase considerably in size during pregnancy, but during the latter half of gestation they become softer and flatten out, so that tumours which are low down in the uterus and pelvic in position may rise above the pelvic brim; a myoma which during the last month seems likely to obstruct labour may become completely suprapelvic during the first stage of labour. Although the large majority of patients suffering from uncomplicated myoma succeed in reaching term, many of them suffer considerable discomfort from pain or haemorrhage which in rare instances may necessitate operation. Myomeotomy is indicated in conditions which cause great suffering or point to danger to the mother, the foetus, or both, such as torsion of a subserous myoma followed by necrosis, prolapse and impaction of a subserous myoma in the pelvis, or forcing of the uterus by an anteriorly situated myoma into a position of retroflexion likely to cause abortion or incarceration. The writer considers it inadvisable to attempt the removal by myomeotomy of an interstitial myoma of any size or of one which necessitates opening the uterine wall down to the membranes. The cases suitable for myomeotomy are those in which the myoma is subserous, and the more pedunculated the tumour the more favourable is the prognosis. Cases requiring hysterectomy are usually those of large fibroids, especially when situated in the pelvis, or of smaller myomata causing intolerable pain. At the time of parturition, Caesarean section is the correct procedure in the presence of a fixed obstructing myoma; if a future myomeotomy leaving a serviceable uterus seems possible, the fibroids should be left *in situ* to be dealt with when involution is complete. In cases, however, which, as a result of repeated examinations or injudicious attempts at delivery, are likely to have been infected, Caesarean section should be followed by immediate removal of the uterus; the same is true if the number or configuration of the myomata is such as to render subsequent myomeotomy inadvisable. In the third stage of labour and in the puerperium, haemorrhage is the more common and sepsis the more dangerous of the complications which may be encountered; the former occurs *post partum* both with interstitial and submucous myomata, and also as secondary haemorrhage during the puerperium in connexion with submucous myomata.

242. The Cause of "Idiopathic" Haemorrhage.

ACCORDING to DE ROUVILLE and SAPPEY (*Gynéc. et Obstét.*, 1921, iv, 5), uterine haemorrhage occurring in the absence of general or local pathological conditions, such as syphilis, heart disease, villous metritis, polyps, fibroma or carcinoma, has been ascribed of late years to abnormalities of ovarian function due to variations in the internal secretion produced by the lutein cells of the internal theca of the Graafian follicles and of the corpus luteum. As evidence for this view may be quoted, the lack of success attending curettage and other therapeutic measures, the results of ovarian grafts and of oophorectomy, and the disappearance of idiopathic haemorrhages after radium treatment or x-ray therapy, both of which owe their efficacy to ovarian castration. The authors find additional evidence from the results of histological examination of a series of fibrocystic ovaries extirpated at operation. Such ovaries may be assigned, they remark, to one or other of two clearly marked groups, of which the former corresponds to a clinical history characterized by excessive uterine haemorrhage, and the latter to a symptomatology in which pain is conspicuous, but notably abundant haemorrhage is absent. In the former group of cases the ovary shows invariably an excessive production of lutein cells, which are to be found both in the internal theca of atretic follicles, and also in the form of isolated groups distributed throughout the ovarian stroma; they also occur in abundance in the thickened wall of corpus luteum cysts. In the second group of cases, on the contrary, lutein cells occur sparsely, and the cystic follicles show a wall which contains hyaline or connective tissue elements with few gland cells. The uterine lesions, to which responsibility was formerly

assigned for cases of idiopathic haemorrhage, probably consist solely in pre-menstrual or post-menstrual variations. Although formerly sceptical, the authors conclude that the ovarian source of the haemorrhage in the cases under review is now well established.

243. Hegar's Signs of Pregnancy.

MOENCH (*Amer. Journ. of Gynec. and Obstet.*, December, 1921) is in agreement with Hegar and his pupils in stating that the presence in their typical form of the Hegar signs may be taken as indicating definitely the existence of pregnancy. Both signs are due to the softening and increased compressibility of the lower uterine segment at a time when the uterine cavity is mainly occupied by the amniotic sac of fluid. Hegar's second sign has been almost forgotten, but, according to Moench, has as great value as the first sign. It consists in the production of a fold in the anterior wall of the lower uterine segment when this region is manipulated between the index finger placed in the anterior vaginal fornix and the fingers of the other hand pressing backwards above the symphysis pubis. The only disadvantage attaching to this sign is that to elicit it the uterus must be steadied through the abdomen by the hand of an assistant.

244. Development of Myoma after Ovarian Grafting.

FLEISCHMANN (*Zentralbl. f. Gynäk.*, January 21st, 1922) records a case which is of interest in connexion with the views of those who ascribe to the ovary important influences on the nutrition and functions of the uterus. The patient, a nullipara aged 34, had suffered from amenorrhoea for fourteen years; the acutely anteverted corpus uteri and the cervix were noticeably small. Portions of the ovaries removed from a patient aged 44, in whom supravaginal hysterectomy was performed for uterine myomata, were transplanted, and placed among the abdominal muscles of the first subject. Two months after operation this patient had put on 1½ kg. in weight; four months after operation the implanted ovaries were no longer palpable, but the uterus had become perceptibly larger. Five months later the body of the uterus had attained the size of a four weeks' pregnancy, and a myoma the size of a walnut was palpable. In the eleventh and twelfth months after operation definite menstrual symptoms and signs were noticed.

PATHOLOGY.

245. The Experimental Production of Purpura.

REDSON (*Journ. Path. and Bact.*, January, 1922) has amplified his previous work on the experimental production of purpura by means of an antiplatelet serum. Using guinea-pigs he studied the effect on them of the injection of an anti-red-cell, an antiplatelet, an antileucocyte, an anti-whole-blood, and a precipitating serum, paying particular attention to the alterations produced in the counts of the red and white corpuscles and of the platelets during life, and to the presence of haemorrhages on the serous membranes and viscera after death. From these experiments two main facts emerged—namely, that of the five serums employed only the antiplatelet and the anti-whole-blood serums were able to bring about a reduction in the platelet count, and that only in those cases in which a reduction in the platelet count had been produced were haemorrhages found *post mortem*. By absorbing out the red cell agglutinin from an antiplatelet serum, he was able to show that haemagglutination played no part in the causation of purpura. But that a mere reduction in the number of platelets is insufficient of itself to bring about the purpuric condition is shown by the fact that the intravenous injection of peptone or of agar-serum, both of which cause a definite fall in the platelet count, fails to produce it. There must be some other factor at work besides the variations in the platelets. This factor he considers to be probably a degeneration of the endothelial lining of the blood vessels secondary to the action of some toxin. Injuring the endothelium in a young rabbit by the intravenous injection of anti-rabbit-red-cell serum, and subsequently bringing about a removal of the platelets from the circulation by the introduction of agar-serum, produced the typical picture of experimental purpura.

246. A Phenolphthalein Test for Haematuria.

JOHANNESSEN (*Ugeskrift for Læger*, December 8th, 1921) comments unfavourably on the fact that, though the guaiacol test for blood in the urine has repeatedly been proved to be unreliable and misleading, it still survives. He has carried out a series of comparative tests with benzidin, fluorescein, and phenolphthalein, and he has found the last named provide the most delicate, simple, and specific test. To 1 gram phenolphthalein he adds 25 grams hydrazo-benzene (potassium

hydroxide) and 100 grams distilled water. This solution is decolorized by boiling with 10 grams of zinc dust. It is filtered and then an equal quantity of 96 per cent. of alcohol is added to it. This solution keeps for at least half a year. Just before use 1 c.c.m. of oxydol (hydrogen peroxide) should be added to 9 c.c.m. of the solution. The test is extremely simple; to 0.5 c.c.m. of the solution an equal quantity of urine is added, and if it contains blood, a red colour, varying from pink to carmine red, is obtained. Of the many drugs with which the author has tested this reagent, only copper salts gave the same reaction, and test tubes which have been used for examining for sugar should therefore not be employed. The author has worked out a quantitative test: using always the same quantity of the phenolphthalein solution, he adds to it 1 drop of urine; if this gives a positive reaction, he dilutes the urine with distilled water, and continues to do so till 1 drop of the diluted urine ceases to give a positive reaction. Using this quantitative test, he has been able to follow the amount of blood excreted from time to time in the urine of his patients, and he believes that this quantitative control of haematuria may prove as useful as the quantitative control of albuminuria. The test is so delicate that it is positive when there are only 150 to 250 red cells per cubic centimetre of urine, and when only 1/20 to 1/30 of 1 c.c.m. of blood has been added to 1 litre of urine.

247. The Unity of Herpes.

THE researches of more than one observer have now shown that if the contents of a herpetic vesicle be applied to the scarified cornea of a rabbit, the animal will develop a keratitis and in the course of a few days will die of encephalitis. From its brain the virus can be recovered and used to propagate the disease through a series of fresh rabbits. Employing this method as a test of the identity of the virus encountered in human cases of herpes, TEISSIER, GASTINEL, and REILLY (*C. R. Soc. Biologie*, January 14th, 1922) have investigated a number of patients who were suffering from symptomatic herpes occurring in such illnesses, as cerebro-spinal meningitis, acute pneumonia, diphtheritic angina, influenza, catarrhal jaundice, and mumps, as well as in genital herpes appearing in the secondary stage of syphilis, with the result that they find a close similarity existing between the actions of each virus. Control experiments carried out with the contents of vesicles from polymorphous erythema, varicella, or zona were completely negative. It is probable, therefore, that there is no difference between spontaneous and symptomatic herpes. The appearance of the vesicles during the course of an infectious disease must be regarded as a definite complication caused by a different organism from that which has given rise to the primary disease. They conclude by asking why it should be so common to meet with herpetic lesions in cerebro-spinal fever and in pneumonia, while in other diseases, particularly in those which are suspected to be due to a filter-passing virus—such as scarlet fever, variola, and chicken-pox—the occurrence of herpes is quite exceptional.

248. An Experimental Study of Lethargic Encephalitis.

A REVIEW of their most interesting work on the subject of encephalitis is given by LEVADITI, HARVER, and NICOLAU (*Ann. Inst. Pasteur*, January, 1922). Briefly, the results may be recorded as follows: The disease is caused by a virus which is able to pass through a bacterial filter and is resistant to glycerin. It is present in the nasopharyngeal secretion of the patient, as is shown by the fact that if this secretion is rubbed on to the scarified cornea of a rabbit the animal dies in a few days from encephalitis. The period of incubation in this animal is characterized by fever, by a polymorphous nuclear leucocytosis, and by an increased fragility of the red cells. The virus travels from the cornea along the optic nerve to the brain. Certain anaesthetics, such as chloral, ether, and chloroform, shorten the incubation period and aggravate the evolution of the disease. Pathologically, the experimental disease in the rabbit may be divided into two phases: in the first the brain shows an infiltration of polymorphous, while in the second or more chronic stage the mononuclear elements abound, either in the meninges or as cellular cuffs around the vessels. The virus is able to retain its vitality for a long time in water, milk, or in the dried condition; it is destroyed by bile and by antiseptics such as potassium permanganate; it is capable of transmitting the disease when inoculated in even very small quantities; and it does not appear to be diffusible in either glycerin or gelatin. The most marked affinity of the virus seems to be for the cornea and for the skin, and it is interesting to notice in this connexion that both of these structures, together with the central nervous system, are derived embryologically from the ectoderm. So far it has not been encountered in the blood, lymphatic or salivary glands of infected animals. The relation which this virus bears to those of rabies, small-pox, and poliomyelitis is not dealt with in this memoir.

"SOLUS" HEATING COMPRESS

¶ We have made arrangements for large supplies of these Compresses, and can, in consequence, supply at the following competitive prices:—

100 v. "Solus" Compress	...	£1 1 0 each.
200 v. " "	...	£1 2 6 "
250 v. " "	...	£1 3 6 "

Size approximately 15" × 12"

¶ Each Compress is provided with a 3-way switch for control of heat, and when full on is capable of a temperature of 200/220 degrees.

¶ They are made so that they can be fitted to any plug or lamp socket, and consume an amount of current equal to the ordinary 100 c.p. half-watt lamp.

Albulactin

In bottles
at 3/6 & 7/-

Members of the medical profession with past experience of the value of Albulactin in infant feeding will be interested in the announcement that the preparation is again available.

The present day Albulactin is precisely the same as the original product—just pure, sterile, soluble lactalbumin—the vital proteid of milk.

By its addition, properly-modified cow's milk assumes all the essential characteristics of human milk, because the percentages of casein and lactalbumin are correctly balanced and the production of a finely sub-divided, easily-digested curd is assured.

All enquiries respecting Albulactin should be addressed to

A British Medical Association Lecture ON "PERNICIOUS ANAEMIA" AND "SEPTIC ANAEMIA."

ON NEW OBSERVATIONS ON THE DISTINCTIVE SORE TONGUE,
SEASONAL INCIDENCE AND POWERS OF RECOVERY OF
"PERNICIOUS ANAEMIA," NOW TERMED
"GLOSSITIC ANAEMIA."

WILLIAM HUNTER, C.B., M.D., F.R.C.P.,
SENIOR PHYSICIAN, THE LONDON FEVER HOSPITAL; CONSULTING
PHYSICIAN, CHANCING CROSS HOSPITAL.

INTRODUCTORY.

THE subject of anaemias, selected by the Council of the British Medical Association for my address to you to-day, has been one of peculiar interest to me for over thirty-five years. In coming back to it now after a break in that interest occasioned by the war, I have put to myself the question, what has been the practical outcome of it all? And I have thought that I might best help it if I endeavoured to day to consider before you what new light, if any, this prolonged study has thrown either on the nature, the diagnosis, or the treatment of those forms of anaemias that are obscure and trouble both in diagnosis and treatment—forms best signified as severe to distinguish them from others that are simple in their character.

In my remarks to you to-day I shall draw on my experiences, and illustrate them by the specimens and plates shown to you, without adhering to the final form which I have sketched out and now give to this address. The former easy to me, while the latter, owing to the abundance of material at my disposal, is difficult. And yet I feel a great desire to put together in the form of one address the salient facts of that experience, in the hope that by so doing I may give you something that may help you in your outlook and action in connexion with blood diseases generally and severe anaemias in particular.

The infective and clinical features of severe anaemias go deeper into their nature and help far more in diagnosis and treatment than the various blood criteria so much before us in dealing with anaemias. Such sums up in one sentence the most important outcome of my studies, and may well be taken as the text of my address to you to-day.

I am not going into the matter of these blood changes with you to-day. Indeed, in all my various studies and writings have kept them in the background. I have had a great purpose in doing so. As detailed in the formidable list of percentages familiar to us in blood reports they make a deep impression on the eye and on the mind—that surely here, if anywhere, the full facts regarding anaemias must be found. Unfortunately this is not the case. For they have one great drawback—namely, they always fail precisely in the hardest and group of cases, in which the clinical observer most needs their help. Secondly, they always fail whenever the anaemia is moderate in degree, and when it is particularly necessary to be sure of the character of the anaemia with which we have to deal if successful measures are to be taken in time to arrest its progress.

Infective Criteria.

On the other hand, the outcome of the study of the infective clinical features presented by cases of severe anaemia has added me the following information, which I summarize in a few paragraphs, and shall afterwards amplify in the course of my address:

1. Two forms of severe anaemia are to be recognized. The one is the great haemolytic disease, *sui generis*, termed idiopathic or pernicious anaemia. The other is a very common anemic condition—non-haemolytic in its nature—which I have differentiated and term septic anaemia (1900). It is these two classes of severe anaemia with regard to which I propose to-day to describe the final outcome of my studies.

2. That outcome reveals that the patient who presents the picture of desperate anaemia—termed pernicious, as it was presented and as it is still presented when first seen—is really in the midst of both the above forms of anaemia, each of them capable of killing him, and the two combined absolutely mortal. The chief clue that gives his illness its main characters and clinical features and course is the haemolytic disease, termed pernicious anaemia; the other complicating one is the above-mentioned non-haemolytic anaemia.

* Delivered before the Devon and West Somerset Branch at Taunton, October 15th, 1921.

3. The practical outcome of this recognition and differentiation which I propose to describe to you to-day is that the two anaemias can be torn apart by removing completely the septic anaemia and its causes from the pernicious anaemia patient. On doing this the great haemolytic disease which remains shows itself for the first time in its history in its true uncomplicated characters and course; and these prove to be much milder in severity and with a much better prognosis than were ever formerly presented.

4. The further outcome of these studies has been to reveal certain simple an features which enable the " to be recognized in its " of its first contraction, "nia has been ever dreamt of, and on an average about two years before it generally comes under treatment.

5. The infective and clinical features here referred to, that help so much in diagnosis and treatment of both classes of anaemia, are connected with observations, not on the blood, but of lesions connected with the mouth. These lesions are combined in the case of the pernicious anaemia patient, but are perfectly distinct from one another, and have a totally different pathological and etiological significance.

The infective lesions connected with, and diagnostic of, the haemolytic disease "pernicious anaemia" are those connected with, and manifested by, the peculiar sore tongue which this disease presents as one of its earliest features. The lesions concerned with the "septic anaemia" are septic lesions connected with chronic and overlooked, dental and nasal sepsis, especially the former, to which I have given the name "oral sepsis."

The foregoing being a brief summary of the general outcome of my studies, I now pass on to consider some of the chief facts in the following three sections of my address; Part I: Pernicious anaemia. Part II: Septic anaemia, as an independent anaemia, and as an intense complication of pernicious anaemia. Part III: Great powers of recovery of pernicious anaemia on removal of the sepsis and septic anaemia associated with it.

I.—PERNICIOUS ANAEMIA.

Sore Tongue as the Earliest and Chief Diagnostic Feature of Pernicious Anaemia.

The particular lesion which more than any other I find to be most distinctive of the haemolytic disease "pernicious anaemia" is the presence or history of a peculiar form of "sore tongue" in a patient suffering from an anaemia. Such a history, associated with the clinical features of increased blood destruction (haemolysis), is, in my observations of the past thirty years, since I first described it in the first case I ever studied (1890), the most important infective and diagnostic feature of this great haemolytic disease. So much is this the case that the name which would, in my judgement, most clearly connote this disease, help in its early recognition and subsequent control, and at the same time get rid of the brutal, ill-omened, prognostic, and confusing name of pernicious, would be the title "Glossitic haemolytic anaemia," or, more shortly, "Glossitic anaemia." After many years of perplexing consideration given to the matter, it is that name I now give this disease, and by which I shall henceforth refer to it. I do so in the hope that I may thereby free future observers and future sufferers from this disease from some of the difficulties which for thirty years and more I have experienced in connexion with the name "pernicious"—the worst name ever given in medicine, and a cause of confusion not associated with any other disease in medicine.

The name "glossitic" which I now give it will at least make clear the exact identity of the haemolytic disease, with which my work for thirty years has been concerned—the disease which alone I have ever had in view under the name "pernicious anaemia," or the more distinctive name of idiopathic anaemia of Addison, or the historical name I gave it in my work in 1910 of Addisonian anaemia, or the latest name given to it in an important Continental work in Holland of Addison-Hunterian anaemia.

The great haemolytic disease to which I thus give the name of glossitic anaemia is the disease referred to throughout its history by the following names:

- "Anaemia in its most idiopathic form" (Combe, 1822).
- "Idiopathic anaemia" (Addison, 1855).
- "Progressive pernicious anaemia" (Swiss and German and other observers, 1870-88).
- "Idiopathic pernicious anaemia" (Pry-Smith, 1878).
- "Pernicious anaemia" (all observers).
- "Idiopathic haemolytic anaemia" (Hunter, 1890).
- "Addisonian anaemia" (Hunter, 1910).
- "Addison-Hunterian anaemia" (two chief Dutch writers, 1921).
- Idiopathic "Glossitic anaemia" (Hunter, 1921).

In bringing to an end my long series of studies on this disease and giving it now this final name, may I note that by an interesting coincidence the disease this year celebrates the centenary of its first case recorded in any language—namely, that recorded by Combe of Edinburgh in 1822.

May I note further that the very first words he applied to the disease were: "A very peculiar disease, which will doubtless be viewed in different lights and receive different appellations. If any train of symptoms may be allowed to constitute anaemia a generic disease, the following may be considered an example of it in its most idiopathic form."

May I add, further, the final opinion of the oldest observer who had followed its story for a period of nearly sixty years—from its earliest beginnings in English medicine in the late "forties" of the past century to the final termination of my own work upon it in 1903. The observer referred to was Professor Sir William Gairdner of Glasgow (1903), who said, writing a year or two before his death:

"My earliest acquaintance with the disease dates from the late 'forties,' when I reviewed the first paper in which Addison introduced his idiopathic anaemia idea. All I have seen makes generally for your view of the case. I wish I had taken note of the glossitic phenomena you describe, but I am afraid I am among the number of those who have passed over very much within my view. If you can make that point (the glossitis) clear as being of the frequency you describe, you will have won your case against all gainsayers."

In introducing this name, may I, to save time, anticipate the criticism which I know from past experience of everything connected with the name "pernicious" will assuredly be raised. That criticism is that I have described a "new form" of pernicious anaemia, thereby only making confusion worse confounded. To anticipate this may I repeat that, apart from the disease to which I now give the name of "glossitic anaemia," I have never seen a case of "pernicious anaemia" in my life, or a case of "idiopathic anaemia of Addison," or a case of "Addisonian anaemia," or a case of "Addison-Hunterian anaemia."

What I have done is to obtain the great haemolytic disease in a pure form such as rarely, if ever, previously existed; to find that this disease when freed from sepsis has milder characters and a more benign and better course than it ever before had, and that it deserves some name that will help in its diagnosis and treatment, instead of the name "pernicious," which does neither.

May I also anticipate another kind of criticism which it may at once receive. It was one I heard recently from a student. He had evidently been taught to attach no importance to it, because, as he said, a similar sore tongue could also be found in sprue, scarlet fever, and leucoplakia! Sprue, a disease of which most people have never seen a case; leucoplakia, a condition which is of no vital importance to anyone; and scarlet fever, of which I have seen many thousands of cases, and with whose tongue conditions, it may be presumed, I am well acquainted. The sore tongue to which I attach importance is that found in combination with the twenty-one characteristic clinical features of the disease I term glossitic anaemia.

Sore Tongue Features in Ten Cases.

The sore-tongue lesions I refer to are those I described for the first time in the first case of the disease I ever studied (1890). Their histological characters are illustrated in my work on *Severest Anaemias* (1910), in plates which I now show you. Their constancy is such that I have seen them in every case—150 or more—of which I have full records. Their characters when marked are shown in the coloured plate from the last case under my observation. Their relation to the disease from its origin onwards may be illustrated by the following cases selected almost at random from my records.

CASE I. (*The Original Case, 1889.*)

Illness dated from the autumn of 1887. While on holiday in the country he was exposed for a time to unhealthy sanitary conditions—drain smells. He suffered at the time from sore tongue and sore throat, and never afterwards regained his health.

1887. He continued to suffer at times from an inflamed tongue—red spots on the tongue.

1888 (June). His tongue troubled him very much, tenderness on eating, extending down the throat into his stomach. Tongue extremely flabby, indented by the teeth, presenting a red fiery appearance, with scattered patches of a more inflamed character. Portions of the mucosa being smooth as if devoid of papillae. The redness extended to anterior pillar of fauces.

May, 1889. Tongue much the same as before, not quite so raw; along edges there are patches of more fiery redness. Some of these under tip of tongue show small inflamed vesicles full of serum. (Death took place in May, 1889.)

CASE XII (1901).

About September, 1900, very bad inflamed tongue, deep red, swelled so that he could hardly get it out of his mouth, and he took everything cold—anything warm gave him pain. Tongue always more or less tender for some years before—always on the same spot, the right side; with sometimes little vesicles. This came and went, but was never severe till September, 1900, when the attack lasted six weeks. Has not been troubled with it since till now (May, 1901), when it became sore all over and is still sore. It is now smooth and glazed. (Death, 1901.)

(Illustrations of this tongue in *Severest Anaemias* (1910), Plate 2, Fig. 4; Plate 5, Figs. 9 and 10. The changes were extreme in character, nearly all the muscle substance being destroyed, and the epithelial covering reduced to a mere line of cells.)

CASE XV (1901).

A gentleman, an eminent member of the profession, living retired in a large old country house with sporting estate attached. He was fond of gardening. In the autumn of 1900 he spent much time in watering his roses with sewage obtained from an cesspool, the stench of which was very bad. His tongue became very sore, and at the same time he began to feel very weak and tired at the end of the day. He had formed a small sitting-room from a former gun-room, with which an old lavatory was connected. He used to sit, feeling very weary, by the fire in the room, between the fire and the lavatory. He then found that there was an old cesspool under his lavatory floor, so that, unknowing, he had again exposed himself to very marked drain infection. He became very ill and anaemic during the autumn (stage of invasion). He had all the features of pernicious anaemia the following spring when I saw him, accompanied by the recurrent sore tongue. I made a remarkably good recovery three months after I saw him and enjoyed excellent and robust health over a period of eight years, when he died.

He wrote me that he still from time to time had feelings of intense illness, which gave him concern, and a feeling that he still had his old disease on him. I saw him only once, some six years later, in robust health. His tongue was beefy red and very characteristic. He died two or three years later, but I never got any further details.

CASE XIX (1901).

Month becomes sore every three or four weeks with what appears to be little "canker spots" on sides; tongue swells and cracks. This lasts about a week, then goes off for a time.

January, 1902. Tongue much better, sores on sides healed, but surface shows a sodden appearance.

February. Patches on side of tongue returning.

March. Tongue better and clean. (Death. Illustrations of tongue, op. cit., Plate 2, Fig. 3.)

CASE XX (1901).

Ill health began in 1898 when she went to stay with friends and slept in an insanitary room for a month. On returning home complained of a sore tongue (incubation period of disease; three to four weeks). It was swollen and raw, so that she could not bear to touch it, a number of ulcers—eight on one side alone—extending all round edges of the tongue, inside the cheeks, and on the throat. She has had this condition off and on ever since about every two or three weeks. Tongue now soft, with angry red patches on side and tip; at other parts shows atrophy. At two parts, small whit patches, like sodden blisters, very tender. Tongue at times swell up almost to teeth.

February, 1902. Tongue very clean.

March, 1902. Three red spots on tongue at tip. On left edge two yellow vesicles about size of a barley seed. Later on improvement and no redness.

CASE XXV (1902).

For last two years "she has always had a sore tongue, so that she could not take wine without a feeling of scalding as far as the stomach." It comes and goes; no vesicles, but little cracks appear on edges and on dorsum. Tongue has now a singularly inflamed look, with cracks all over the edges; great tenderness.

CASE XXVIII (1903).

Tongue became sore about three months ago (September); soreness seems to go right through to back passage. It appears perfectly well for a time, then a relapse occurs once in two or three weeks. It has now a smooth and fissured appearance.

CASE XXXIV (1905).

Ill health began some four years ago (1901), when he had a bad attack of anaemia. Tongue has been sore off and on since 1901. Always noted at the times he is ill. Then the pain goes down to pit of stomach, causing retching and indigestion; then he gets so weak he has to go to bed.

CASE XLIV (1907).

Good health till spring of 1903, when she came in contact with a very foul drain. Tongue at this time began to be sore and red, varying in intensity and distribution; and this has continued up to present time with periods of intermission.

CASE XLVII (1907).

Since 1905 tongue has been very sore—very beefy-looking. Sometimes blood raw. Comes and goes every few weeks. Soreness extends down into stomach, with severe diarrhoea.

1908. Tongue remarkable—bright, fiery red, with cracks on side and bright red papillae all over.

September. Run down in health and had a bad tongue. Tongue gets inflamed at tip every three weeks, accompanied by some discomfort in stomach and lower down, as if he were inflamed all the way down.

Summary.

I have found a history, similar to the preceding, in all cases I have seen.

It may be summed up as a sudden onset, with a seasonal one of onset (July to September), marked by periodic "sore tongue," periodic "sore stomach," periodic "sore bowel," followed by periodic sore haemolysis, periodic sore anaemia. The first three features occur singly or combined, varying in intensity at different times; sometimes quiescent, at other times active. This periodicity is very marked in the tongue lesions. At times this looks quite normal; but at other times, generally at intervals of two to three weeks, it becomes tender, and shows patches of redness, or vesicles; or it may become extremely inflamed, looking like raw beef. When the patient is extremely anaemic these tongue lesions are least obvious, since the patient has not sufficient blood in his body to cause redness or inflammation; and in some cases they may be quite absent or quiescent for months at a time. They are therefore often best seen when the patient is comparatively well or in the stage of recovery. Their recurrence from time to time during the stage of recovery is a most valuable guide in the treatment of the case, since it denotes renewed activity of the disease at different times. These recurrences are always accompanied by evidences of haemolysis—for example, lemon colour, high colour of urine, and some fall in the number of red cells—as observed over a period of fifteen years in a case under my care, which I shall later refer to.

I show you the actual changes in the tongue (and stomach and intestine) as represented in plates in my work, *Severe Anaemias* (1910). The intrahepatic changes of catarrh of the smaller bile ducts associated with the jaundice (haemolytic) occasionally presented by the disease I have also been able to study in a case which died in the acute stage.

Clinical Features and Course of the Haemolytic Disease "Glossitic Anaemia," ushered in by the above Symptoms of Recurrent Sore Tongue.

The disease thus ushered in is the anaemia termed pernicious anaemia. Apart from the disease marked by sore tongue above described, I have never seen a case of pernicious anaemia in my life. As regards the individuality and identity of this disease, I draw special attention to two outstanding etiological characters distinguishing it from other anaemias.

Individuality and Identity of this Disease.—The first is its most peculiar sex and age incidence in the 150 cases—no fewer than 71 per cent. of the cases being in men, in whom all other anaemias are least common; and 85 per cent. over the age of 40, the age at which all other anaemias are least common. This feature is a hard statistical one, which can be expressed in actual figures as above stated. The haemolytic and glossitic features which, from 1890 onwards, I have described in connexion with this disease I have now called glossitic anaemia, have lifted the identity of this anaemic disease far above the level at which it stood thirty years ago under the title of "pernicious anaemia." The sex and age incidence originally given for the anaemia called by this name (in 1871) was 20 per cent. in the male sex (as compared with my 71 per cent.); and 16 per cent. above the age of 40 (as compared with my 85 per cent.); obviously a totally different class of cases. Nevertheless, in spite of this extraordinary difference, the name I have to give the unique type of disease which forms my group of cases is the same name "pernicious" as that given to a totally different class of case. Hence my resolve now—after thirty years of difficulties connected with the above fact—to give this great haemolytic disease a name that will accurately connote its identity as I find it, and also incidentally connote the disease to which all my work on this disease refers.

The second great outstanding feature of this disease is the last one I described in connexion with it—in 1913. This is the extraordinarily marked seasonal character of its onset and of its periodic relapses—namely, July to September for its onset, and approximately the same months, July to September, for its relapses. I know nothing in connexion with any chronic disease so remarkable or so constant. It places this disease within the category of specific infective diseases in such a striking way that this character of it can be no longer in doubt. No other anaemia known to me has such a character. It is notably absent in the anaemic condition which, when severe, most closely resembles it, and is most frequently mistaken for it—the anaemia which I have differentiated and term "septic anaemia."

All my cases show the same characters and course as the original one. But many show certain other features to which I draw special attention. The first of these is the occurrence of fever as one of the first features in the onset of the disease—fever of obscure nature, generally termed "influenza" by the patient. This feature is quite a common one. Its chief character is that it is followed by such a surprising degree of weakness and by the lemon colour which denotes the haemolysis of the disease.

Another feature shown in other cases is one of great importance—the surprising degree of anaemia which accompanies this first attack, down to 40 per cent., a fact of importance since it is very seldom that the blood is examined at this period. The same applies to the second attack, which is often also passed through without the question of a severe anaemia having been raised; and yet the blood may be as low as 23 per cent. The recovery from this attack is not so rapid or complete as after the first attack, the blood only rising to 50 or 60 per cent. as compared with 80 to 90 in the first attack.

It is generally only when the third attack occurs that the anaemia becomes so marked as to be a matter of real concern. The question of it being "pernicious" is then raised often for the first time—that is to say, two years after the original attack. It is quite astonishing, indeed, to see from one's reports how often the patient's statement begins that his "illness began about two years ago." It is this important hiatus in the observation and possible control of the disease that can now be bridged over by the diagnostic feature of the sore tongue which I have described. For the patient can often recall, even to within a month, the exact date at which he first began to be troubled with a "sore tongue," and that occurrence marks approximately the first period of onset of the disease.

Lastly, a constant feature is the existence of nervous features in slighter or severer degree in all cases of the disease—visceral pains (in tongue, stomach, or intestine), peripheral, cerebral and mental.

II.—SEPTIC ANAEMIA:

(a) AS AN INDEPENDENT ANAEMIA;

(b) AS A COMPLICATION OF PERNICIOUS ANAEMIA.

Interesting and informing as the foregoing facts may be regarding the great haemolytic disease, an even greater interest and practical importance attaches to the second outcome of my studies regarding anaemias. That outcome is the complete differentiation of another form of anaemia which I have termed septic anaemia: and the discovery of the great part it plays not only as an anaemia existing by itself, but even more as a frequent accompaniment and complication of other forms of anaemia, and indeed of other diseases.

Its discovery arose out of my studies (in 1900) regarding the presence of the common septic conditions I termed oral sepsis as an intense complication—not the causa causans (pace many erroneous statements)—of the great haemolytic disease pernicious anaemia marked by sore tongue, as I have described in the previous section. I find, namely, that this oral sepsis itself can and often does cause a form of anaemia quite different from the haemolytic anaemia of the sore tongue disease. The anaemia so caused is not an anaemia *sui generis* as the former is; it is an anaemic condition produced by long-standing sepsis—chiefly streptococcal—such as accompanies dental disease, or may be found from time to time in adjacent parts, especially the antrum and nasal air sinuses.

This septic anaemia is, in my experience, the commonest form of all anaemias. It varies much in degree, often mild, but at times very severe, simulating and approaching even that of the sore tongue, haemolytic anaemia—for example, down to 20 per cent. of red cells. But it differs totally in its pathology from the above-mentioned glossitic (or pernicious) anaemia in being non-haemolytic, and in owing its character to deficient blood formation, just as much as the haemolytic anaemia owes its character to excessive blood destruction. The cause of it in nine-tenths of cases is, as I have just stated, unrecognized and very common sepsis, connected with bad teeth and periodontal disease (pyorrhoica)—"oral sepsis"; in other cases it is overlooked sepsis in the antrum and nasal sinuses.

But, as I have stated, the intense clinical interest of this anaemia is that it may not only exist alone. Far more frequently it exists along with and complicates other anaemias in which similar conditions of oral sepsis are present, and herein lies part of the great importance of oral sepsis in connexion with the disease called pernicious anaemia.

"Glossitic Anaemia" plus "Septic Anaemia" in the same Patient: Importance of Oral Sepsis as a Complication.

In addition to the history or presence of sore-tongue lesions, which I regard as of utmost diagnostic importance, the mouth in glossitic anaemia patients generally presents when first seen another class of infective lesions connected not with the tongue but with the teeth. There are the septic conditions which I term "oral sepsis" (1900). I have kept them apart from the glossitic lesions because they are of a different character and significance. However bad they may be they do not in the absence of sore tongue or its history point to the diagnosis of the idiopathic haemolytic disease, glossitic anaemia. On the other hand, any history of sore tongue, however slight it may be, in an anaemic patient should raise the suspicion of this haemolytic disease, even if little or no oral sepsis is present.

In most cases, however, the conditions of oral sepsis presented when the patient first comes under notice are very bad. Thus to quote only one case:

"Many of his teeth are quite loose, both in the upper and lower jaw; they are all very septic, showing periodontitis, pyorrhoea, and calcareous tartar deposits, and much septic gingivitis, and there are in addition a number of carious teeth and septic stumps. He has neglected his teeth, and has been in the habit of himself pulling them out as they became loose."

A pretty septic story is thus presented by such cases—a story prior to 1900 invariably present in all cases throughout the history of the disease, and still presented in some degree or other by every case when it first comes under notice.

What is the importance of these septic lesions around the teeth? It is, I find, of a threefold character, to which I draw your special attention.

1. *Power of Producing Septic Anaemia.*—The one to which I am specially drawing your attention to-day is the power of chronic streptococcal sepsis *per se* in producing a definite and sometimes extreme degree of the anaemia I have termed "septic anaemia." Important as this is in connexion with the prevalence of oral sepsis and the part it is thus playing in causing all sorts of degrees of anaemia—for example, in young children, young adults, and especially in young girls who are already so liable to anaemia of non-infective nature—this power *per se* of producing anaemia by no means exhausts its special importance as a complication of the haemolytic disease, glossitic anaemia. For in this latter disease the tongue is the seat of lesions which cause cracks and fissures and abrasions of its covering epithelium, exposing it therefore in special degree to any septic infection in the mouth. And when one remembers how constantly the tongue is in movement, expanding and contracting, it must act like a sponge in absorbing the intense streptococcal sepsis present in many cases, thereby favouring the production of septic anaemia. Furthermore, the action of septic infection is to retard blood formation in the bone marrow (a pale bone marrow). It thus counteracts the action of the haemolytic infection, which is to stimulate blood formation (red bone marrow). The removal of the sepsis therefore frees the bone marrow from a markedly depressing influence, and allows the full compensatory powers of the bone marrow free play. The result is shown by the remarkable and increased powers of recovery of the haemolytic disease on removal of the sepsis.

2. *Power of Producing "Septic Gastritis" and "Septic Enteritis."*—In this latter disease oral sepsis plays another important part—the one which first drew my attention to it, and the one which I endeavoured to describe in my first account of this subject in 1900. That part is the power of oral sepsis in inducing unhealthy conditions of catarrh in the stomach and intestine ("septic gastritis" and "septic enteritis," as I termed them)—in the alimentary tract. It is these that constitute the class of "certain favourable conditions" which in my first studies in 1893 I concluded to be necessary for the contraction of the haemolytic infection (a specific one) underlying the haemolytic disease and glossitic anaemia. My studies have fully confirmed the importance of this action of oral sepsis. Prior to 1900 the most distressing features of that disease were the frequency of gastric and intestinal symptoms: the loss of appetite, the distaste for food, the nausea, recurrent sickness and vomiting, the looseness of bowels, or the recurrent and oftentimes persistent diarrhoea which marked the progress of this disease—for example, vomiting every day for two or three months. While symptoms of gastro-intestinal disturbance are still definite features of the disease, I never see nowadays this class in the severe degree I formerly witnessed in every case. All the patients recently under my care have indeed been singularly free from them, except from time to time in slight degree. I attribute this happy result to the removal of all oral sepsis—all teeth from the cases—and to the consequent removal of that factor as a potential cause of gastric and intestinal trouble, or as a potential complication and adjuvant of the action of the specific haemolytic lesions that may be, and in all cases are, present in some part or other of the gastric or intestinal mucosa.

3. *Septic Lesions around the Teeth as Seats of the Haemolytic Infection of Glossitic Anaemia.*—But a third (and in my judgement the most important) part, from a pathological point of view, played by oral sepsis in connexion with the haemolytic disease, glossitic anaemia, is the one I have now indicated. This is that the

lesions around septic teeth, the open wounds connected with septic gingivitis—for example, especially under calcareous masses of tartar—the pyorrhoea; the carious roots, the presence of gold caps or bridges, *et hoc genus omne*, are lesions in which the haemolytic infection of the disease also takes root and by which its persistence in the body is favoured. So important is this that in my observation the first seat of that infection is in all probability in most cases such open septic lesions around the teeth. It incubates itself there, thence spreads to the tongue, which afterwards becomes its special seat, and thence spreads to the mucosa of the stomach and intestine.

In short, the exact pathology of this disease—its mode of spread—could not be better described than in the words used by one patient regarding it:

"His illness began with sore tongue; his tongue always got inflamed every three weeks, accompanied by some discomfort in the stomach and lower down, as if he were inflamed all the way down." Or as another equally well described it:

"Tongue became sore about three weeks ago. The soreness seems to go right through to back passage. It appears to be perfectly well for a time; then a relapse occurs every two or three weeks."

Or as another described it:

"His illness began with sore tongue, quickly followed by yellowish complexion (haemolysis) and great weakness (anaemia). He told several doctors that he thought the sore tongue had something to do with it, but they attached no importance to it."

If this be the character of the haemolytic infection—namely, located in the tongue, mucosa of stomach and intestine, and wakening into activity every two or three weeks—the importance of open septic wounds around the teeth, in the sockets of the teeth, and in the bone around the sockets, as the seats of the haemolytic infection becomes extreme. For this infection is undoubtedly present in the tongue, and must invariably be passing from the lesions of the tongue to the sockets of the teeth. Or, conversely, if preserved in the lesions around the teeth, it must constantly be passing to the tongue (stomach and intestine), grievously aggravating the amount of the haemolytic infection already present.

A *circulus vitiosus* is thus created between the tongue lesions and the oral septic lesions. Therefore this oral sepsis in this great haemolytic disease glossitic anaemia, already characterized by the great persistence of its own infection, is of altogether supreme importance. So great is the part it plays that in my judgement there is no safety from it in this disease except by the radical measure of removing every tooth—whether bad or apparently good—in order to remove all the potential haemolytic infection which may be present in the septic lesions around teeth already diseased, or that may subsequently find root in teeth which, although apparently good at the time, may later on become diseased. I have never failed to see immediate benefit follow the removal of even one or two bad teeth, and great benefit follow the removal of as many as seemed bad or doubtful. But I have never failed to regret, in every case I have seen, when watching its subsequent course—and seeing how persistent the haemolytic infection is—that I have not been allowed to remove all the teeth in the first instance, in order to get rid once and for all of the important potential complication of new seats of infection being formed around teeth as they subsequently become bad.

Frequency of Oral Sepsis in "Glossitic Anaemia."

On this point I have, since I first announced it in 1900, had no manner of doubt—such as many, including not a few teachers, seem apparently to have, judging from what I sometimes hear. Their furthest admission regarding the matter does not go beyond the very guarded and non-committal one that "I am inclined to think there may be something in it, although, of course, not as much as you believe. Why, I have seen cases of pernicious anaemia without any teeth!" (Many such cases are now being seen—since 1900, when the importance of removing septic teeth was first drawn attention to. Further, pernicious anaemia is far more common in hospitals than formerly was the case, for the reason that far more chronic cases are now alive.)

My own doubts have long been dispelled, as theirs also would have been, by the painful and tragic experience I had shortly after 1900 of seeing several scores of private patients in rapid succession in the course of a few years, all of them presenting features of sepsis in the teeth and mouth that were perfectly lamentable. The majority of them were found at death's door, literally sodden with neglected sepsis, in addition to their real severe disease, although on an average they had had their disease on them for about two

ears before I saw them. So bad was it that I found it impossible to carry out the measures of antiseptics and removal of septic teeth which were clearly indicated, albeit at that time doubtfully regarded alike by the doctor and still more by the patient. "It beats me to understand what my teeth are got to do with my disease," as one patient in a desperate state remarked.)

The worst experience was of seeing the great majority of these earlier patients die within an average of three and a half months from the time of my seeing them. Thus, out of my first group of 44 private cases, death occurred in 35 cases: 4 in less than a month (most of them within a few days), 3 within two months, 21 within three months, 25 within four months, 27 within five months, 23 within six months, 31 within seven months, and 35 within eight months.

That picture represents the severity and character of the great idiopathic anaemic disease which throughout my studies I have designated "pernicious anaemia"—the disease which I find to be distinguished by its glossitic and haemolytic features, the disease to which I therefore now give the title of "glossitic anaemia." Such, however, is not the picture which that disease may, since 1900, present if it be freed from sepsis and the septic anaemia which complicates it. It remains the same disease *in genere*. But when thus freed from sepsis it presents milder clinical features and a much better clinical course than anything it was ever capable of showing prior to 1900, before the era of antiseptics in anaemia which then commenced.

Increased Powers of Recovery after Removal of Sepsis.

When sepsis is removed what is the result? Are the powers of recovery of this haemolytic anaemia thereby increased? Are the features or course of the disease when freed from sepsis and septic anaemia in any degree modified from that presented by the disease previous to 1900, when I first formulated my conclusions?

My own experience is that they are notably modified. The full true features of this idiopathic haemolytic disease, when thus freed from sepsis, have been presented to me time and again during the past twenty years, as they never were seen and never existed before. The dreadful, hopeless pictures which it formerly presented I never now see in any of my cases in whom I have been able to carry out the full measures of antiseptics I consider necessary. However severe the disease may be—and it is always severe; however sharp its individual attacks may be—and they can be of the severest character (for instance, the patient lying in a state of unconsciousness and coma for a whole week, the doctor giving no hope, and stating that the patient could not last till the morning, as in one of the last cases seen); I have time and again seen the patient recover, as if by a miracle, and restored in two or three months, sometimes even in a month or two, to an appearance of robust health and vigour, with high colour, high blood count (90 per cent.), declaring that he had never felt so well in his life. (In the case above referred to the patient came and reported herself, apparently a picture of perfect health with beautiful complexion and colour, two months after she had been at death's door.)

These results, indicating better powers of recovery of this disease, may possibly, it may be said, be due to improved methods of treatment of the disease—for instance, to the use of salvarsan, neo-salvarsan, neovarsoumbillon, transfusion, excision of spleen, better methods of giving arsenic, etc., of which one reads from time to time in connexion with the treatment of such cases. But in the group of 150 cases under my care during the thirteen years 1900 to 1913 I have used no new method of treatment other than the antiseptic treatment against gastro-intestinal sepsis, which I recommended for the first time in 1890, and the measures of oral antiseptics which I recommended in 1900. I have only on one occasion injected salvarsan; I have never used the other arsenical drugs of this character; I have never injected arsenic hypodermically; and finally, as regards arsenic, I have never given a dose of more than 5 minims at a time, and my usual dose has been 2 to 3 minims given by the mouth in the form of liquor arsenicalis. If my cases have shown the increased powers of recovery I have above described, as they undoubtedly have, the only new measure of treatment with which their improvement can be associated has been the great, and to my mind the all-important, one of strictest antiseptics above referred to, thereby enabling the disease to manifest its own great powers of recovery when freed from complicating sepsis.

III.—POWERS OF RECOVERY IN GLOSSITIC ANAEMIA.

The outcome as regards the nature of severe anaemia being as I have above stated, the results of the measures of treatment directed to the removal of sepsis may be briefly summed up as follows:

The results show a rapidity, degree, and increased permanence of recovery of "pernicious anaemia" patients under my care of a very striking character, far exceeding anything that I ever saw before 1900, and much more common now than I ever saw up to 1900.

The rapidity and degree of immediate recovery are indeed most remarkable. Formerly I used to be quite pleased when I got a recovery up to 60 per cent. of red cells in the course of four or five months. Now I am accustomed to see rise of from 20 or 30 per cent. up to 60, 70, 80, and 90 per cent. in periods varying from one month up to three months. I show you a few of these results in eight cases of pernicious anaemia selected almost at random—seven of them from cases under my care during the past year of my hospital work. All the cases show a very immediate and striking degree of blood improvement, as will be seen by the rises set out in the following table:

34 per cent. to 76 per cent. in seven weeks, and then 88 per cent. four weeks later.
25 per cent. to 78 per cent. in eight weeks, and then 90 per cent. two weeks later.
35 per cent. to 76 per cent. in nine weeks.
21 per cent. to 78 per cent. in four months.
25 per cent. to 81 per cent. in two months.
27 per cent. to 67 per cent. in four weeks, then up to 90 per cent. four months later, at which level it remained (with three short breaks) for three years, and then continued for fifteen years, when the patient died of another disease.
18 per cent. to 71 per cent. in four weeks, and 102 per cent. in eight weeks.
38 per cent. to 105 per cent. in four weeks.

In comparison with the foregoing I give my experiences in the first 18 private cases I saw (1890-1901) prior to the period of oral antiseptics which I introduced in 1900:

Course of 18 Cases observed, 1890-1901.				
Fatal within 1 month	8 cases.
" " 4 months	13 "
" " 8 months	15 "
" " 1 year	16 "

Increasing Chronicity of the Haemolytic Disease ("Glossitic Anaemia") as shown by Percentage of Red Cells in 171 Blood Counts in 13 Cases at Various Stages up to 15 Years.

Percentage of Red Cells.	No. of Counts.	Percentage of Counts.
105-90	...	10
89-80	14	8
79-70	22	13
69-60	25	21
59-50	26	14
49-40	18	15
39-30	21	29
29-20	18	10
19-8	6	3
		13

I bring out in the foregoing table the most remarkable fact regarding blood changes, probably new to you, to which I draw your special attention. That fact is the increasing chronicity of the disease as shown by the degree of its blood changes. In the mind of everyone the disease called "pernicious anaemia" is specially associated with extraordinarily low blood counts. When we think of it, we think of low percentages of 20 or 30 per cent. causing, as I have had frequent occasion to observe, most extreme alarm. These low counts are undoubtedly presented at some period or other in the course of the disease. But what is not generally known is that these low counts only occur during the acute attacks which characterize the disease, and that these attacks occur generally only once a year. They last a varying period of two to three months. But the acute stage in which the blood count is as low as 20 to 30 per cent. may last only about a month or two; and during the latter part of that period, as I have time and again seen, the patient may be feeling well and on the high road to recovery, even although his blood count remains only 30 to 40 per cent. Moreover, it is during these attacks while the patient is under observation that most blood counts are made.

Bearing the above facts in mind, the most remarkable

result that appears from the above table is that only 13 per cent. of the total counts were below 30 per cent.; 24 per cent. were between 30 and less than 50 per cent.; 29 per cent. were between 50 and less than 70 per cent.; no fewer than 21 per cent. were between 70 and less than 90 per cent.; and finally no fewer than 10 per cent. were 90 up to as high as 105 per cent.

An anaemic disease, in which 31 per cent. of the blood counts in its various stages are over 70 per cent., and 29 per cent. are between 50 and 69—a total of 60 per cent. with over 50 per cent. of red cells, including no fewer than 10 per cent. with percentages between 90 and 105 per cent.: such is the haemolytic disease termed "pernicious anaemia." One might almost say: "Even if one calls it anaemia on account of the degree of anaemia which, when active, it does undoubtedly show, why call it by the ferocious prognostic title 'pernicious,' if, as stated, it may run a course as long as ten to thirteen years, or even longer? Why saddle the sufferer with the unnecessary misery of such a name?"

The facts, in my experience of the disease, are those I have just stated, and the question thus put is one which I think is fully justified. I only know the result—namely, that the dreadful name "pernicious," having been foisted upon English medicine about fifty years ago from German sources, and given to this anaemia, to which English medicine had given the title of "idiopathic" (1855), or still more definitely "most idiopathic" (1822), is still retained, with the result that "it makes the flesh creep" whenever the name is mentioned. It hangs like a gravestone round the neck of the sufferer, not only when he is ill, but also during long intervals when he may not only feel, but actually be, very well.

If this disease throughout its entire course be not characterized by an excessive degree of anaemia, and if the degree of anaemia actually present does not prevent the patient from feeling and being very well, what other name than "pernicious" can be given to it to indicate that even at the times when blood counts are high (for example, 80 to 100 per cent.) the disease is still present, and may in all probability recur if not continuously watched—some name that in the absence of blood changes may indicate its presence or its possible recrudescence? A name that would in the intervals of recovery give this information and help would indeed be a godsend to the sufferer and the observer. Such a name could in my judgement be given to it—a name connoting one of the chief seats of the haemolytic infective process underlying this great haemolytic disease. That lesion is the curious and recurrent sore tongue—one of its earliest and one of its most persistent features—"a most peculiar glossitis," first described by me thirty years ago (1890), characterizing "a most peculiar and idiopathic anaemia."

"Glossitic anaemia" would be the name that would of all others in my experience best connote this great haemolytic disease, help in its early diagnosis even within a few weeks of its onset and in its control by treatment throughout its course, by directing continuous attention to one of its earliest and most constant, most characteristic, and most easily recognized features.

The name "pernicious" which it bears fulfils, on the other hand, not a single purpose connected with the art, science, or practice of medicine. It is false, misleading, hurtful, and harmful; it is mischievous, prejudicial, disadvantageous, disserviceable; it is unlucky, sinister, obnoxious, oppressive, burdensome; it is inauspicious, destructive, and venomous; it is bad, as bad as can be, ill-contrived, ill-conditioned, grievous, deplorable, lamentable, and pitiable; it is wrong, shocking, hateful, detestable, and confounded; it is inadvisable, unprofitable, inexpedient, useless, unskillful, and hopeless.

The measure to which it is all these is such that one of the requests I constantly receive from doctors is not to mention the name of his disease to the patient, as it would unduly alarm him!

If I might be allowed, I would make an urgent appeal to all teachers and writers, in the interests alike of clinical medicine, scientific medicine, the art of medicine, and the practice of medicine, to drive the accursed name out of the nomenclature of diseases, and substitute for it the name which I have finally suggested, which is the opposite of "pernicious"—namely, beneficial, valuable, serviceable, advantageous, profitable, edifying, propitious, hope-giving, fair, genuine, and true; unexceptionable and unobjectionable.

"Pernicious" Traditions.

Such briefly are the features of this disease as revealed to me by my studies for the past thirty-three years—one-third of the total history of the disease. In the case of any other disease of an obscure nature, new facts concerning it would be welcomed, and at once assimilated and incorporated in the body of knowledge regarding it. But in the case of this disease, it may be said that "in vain is any new information

supplied." For the whole ground is already occupied—not by facts, but by firmly rooted traditions, associated not so much with the disease as with the name "pernicious"—pernicious traditions, as they may indeed be correctly termed. These traditions are that the anaemia so called is a mystery: that nothing definite is known about it; that its chief character indeed is that nothing definite can be known about it; certainly that nothing definite can be done for it; that there is little or no hope for its recovery—so little, indeed, that if it does recover it cannot have been the disease. In connexion with it more than with any other disease the current teaching was, and apparently from some recent experiences in examining students still is, expressed in the succinct formula: "Very little is known about this disease"; "Its pathology is not at all known." This teaching has sunk deep into the minds of the profession, and is equally well known to the unfortunate sufferers.

Nevertheless, the actual facts in my experience are that I know of no disease in medicine more clearly defined in all its features from start to finish than this disease; none whose pathology has been more fully worked out in all its many relations (in the blood, liver, spleen, bone marrow; in its striking infective lesions in the tongue; in its neuro-toxic lesions and manifestations); none whose mode of onset, features of invasion, and clinical features and progress from day to day, month to month, and year by year, have been made more clear, or can at any time be more clearly and certainly predicted by me. Lastly, I know of no disease whose study has directly or indirectly led to the introduction of new measures of prevention, treatment, or control, applicable not only to itself but to all other forms of anaemia, and to a whole range of other general diseases.

BIBLIOGRAPHY.

The literature of the disease termed "pernicious anaemia" will be found fully detailed in chronological order in my work on *Severest Anaemias* (Macmillan and Co., 1910). It dates from 1822, when the first case was described.

STERILITY WITH REFERENCE TO THE STATE.*

BY

R. A. GIBBONS, M.D., F.R.C.S.E.,

GYNAECOLOGIST TO THE GROSVENOR HOSPITAL FOR WOMEN.

THOUGH sterility is naturally of keen interest to the individual who is anxious to have a child, it is of more vital moment to the millions constituting the State. The question comes one of national concern, for upon a good average the rate depends the maintenance of the race. The population of a country is estimated by the balance of births over deaths, and immigration over emigration to other countries. It is quite evident that if there is a declining birth rate in any nation, and it is persistent, nothing really matters as to wealth, ability, or accumulation of art treasures, for it is decadent, and must be considered doomed. Therefore everything which science can do to produce healthy bodies, sanitary surroundings, abundance of good food at a cheap rate, and labour with proportionate rest, should be supported by the State. We know that healthy men and women living in edelock should "be fruitful and multiply" if in hygienic surroundings, because congenital sterility or unavoidable sterility is rare, both in men and women. Therefore it has been truly said that the percentage of sterility is the index to the morals of a nation.¹ As we know that of late years the number of children born in each family has steadily declined from its former average it is evident that this matter becomes one of State importance.

I have taken the following from the annual report of the Registrar-General, and, without producing all the figures, may state that in England and Wales, from 1897, when there were 921,693 births, with a rate of 29.7 per 1,000, the numbers have gradually fallen to 668,340 births, with a rate of 17.8 per 1,000, in the year 1917. In 1918 the birth rate was 17.7 and the civil death rate 17.6,² and in 1919 the birth rate was 18.5.

Between 1840 and 1880 the birth rate of England and Wales may be regarded as having been stationary at about 35 per 1,000, so that, compared with the above, the descent to 17.8 per 1,000 is serious. In London alone, from 133,616 births, with a rate per 1,000 of 30 in 1897, there was a fall to 80,554, with a rate per 1,000 of 17.5. Even between 1877 and 1909 there was a reduction of the birth rate in England of over 28 per cent.

The tables of the present official census show that as regards natural increase—that is, the balance of births over deaths—the numbers recorded from 1911 to 1914 may only be compared with those of earlier years, but not later. The fall in the birth rate during 1915 to 1918 was from 20 to 25 per cent. below what might have been expected in normal circumstances, and can therefore be attributed to the war, but the actual amount of the figures during the intercensal period is not nearly sufficient to compensate for the deficiencies of the preceding years.³

The quarterly official return of births registered during the June quarter of 1920 for England and Wales shows 22,417 fewer births than for the March quarter, and of these births 12,132 were illegitimate. In the September quarter of last year there were 15,017 fewer births than in the same quarter of 1920, and 10,466 less in number than in the previous quarter of 1921. Of the births 9,876 were illegitimate.

I do not consider that we are one whit better morally than other nations, although there can be no question about our wishing to appear so in the eyes of those nations. In the case of our illegitimate children we are eager to hide them away, and, in most cases, to allow them to be brought up quite regardless of the future, so that they cannot be in later years claimed by the State, to which they might be of great use.

The following figures will appear rather startling with reference to illegitimate children. From 1897 to 1916 there were in England and Wales 72,443 illegitimate births, the proportion varying from 39.9 to 48 per 1,000 births. It is also interesting to note that from 1910 there has been a steady rise in the proportion of these illegitimate births to the 1,000 of all births, and during the same period there were 174,919 illegitimate births in Scotland, with a percentage varying from 7.04 to 7.1, and 54,801 illegitimate births in Ireland, with a percentage varying from 2.6 to 3.1.⁴

* Read before the Section of Obstetrics and Gynaecology of the Royal Society of Medicine, March 2nd, 1922.

The proof of how little care is bestowed on illegitimate children is afforded by the mortality. Dr. Stevenson found from his record that 45 per cent. of all illegitimate children were the children of domestic servants, and that, whereas the death rate for legitimate children was 0.99 per cent., it was for illegitimate children in general 9.1 per cent., and for the illegitimate children of domestic servants 8.5 per cent. during the first year of life. Dr. Amand Routh⁵ states that the death rate of unmarried mothers and their offspring during pregnancy and the lying-in period is about twice as much as that of married women and their children, which shows how much could be done by better nursing and skilful obstetric help.

In Russia, before the war, I was much struck by the very large foundling hospital which they have in Moscow, admitting yearly about 15,000 children. There any newborn illegitimate child is taken and admitted without any question being asked, except, Has the child been baptized, and if so, by what name? If the child does not possess a name one is given, and although the mother may be nameless, and never known, she has the power of following up the child there by his registration number and claiming him at any time should she be in a position to do so. Thus the children are educated and cared for until the boys go into the army or navy, or are taught various trades, and the girls are trained as nurses or midwives. Hence these lives are saved to the State, whereas in this country, where we have no such institution, for our foundling hospital is not similar, the poor mother, as I have known more than once, has thrown her child on the dust heap to die, or disposed of the offspring in other ways than would have been the case had there been a similar institution where the infant would be cared for.

On discussing the possibility of starting such a foundling hospital, with its excellent clinical work, in this country on my return, I was assured that I could not get any support, that it was a premium upon vice, etc., and so my scheme fell to the ground.

Although the birth rate is falling here, it may be of interest to remark that England is not the only country in which this occurs, as the following table will show:⁶

Country.	Decade of Highest Rate.	Highest Rate.	1891-1900.	1912.
Denmark	1851-1860	37.5	30.2	25.6 (1914)
Norway	" "	35.0	30.4	25.2 (1914)
Finland	" "	35.9	32.1	27.1 (1913)
Germany ⁷	1871-1880	39.1	35.1	14.3 (1918) 27.5 (1913) 22.6 (1912)
Belgium	" "	32.7	28.9	28.2 (1914)
Netherlands	" "	35.4	32.5	31.3
Austria	" "	39.0	37.1	31.3
Italy	1831-1899	37.8	35.3	17.9 (1918)
Hungary	" "	44.0	44.4	35.3
Serbia	" "	45.4	41.9	39.0
France	1801-1810	33.3	22.1	12.1 (19.8) ⁴

⁴ Less Mecklenburg-Schwerin and Mecklenburg-Strelitz.

⁷ 17 non-inhabited departments.

France may be considered as the best example of a pathological birth rate,⁸ but France does not stand alone in showing an abnormally low birth rate.

This general decline in the birth rate cannot be attributed to the postponement of marriage, decrease in the number of those who marry, decrease in the proportion of the total female population which is of child-bearing age, or to diminishing fertility. When all the facts bearing on the matter are carefully considered, we must come to the conclusion that the voluntary limitation in the number of children born is the chief cause of this decline.

As a result of a voluntary confidential census among "intellectuals" it was found that of 120 marriages, 107 were "limited," and 13 "unlimited," and that the average number of children of each marriage was considerably under 2.⁹

A book called *The Fruits of Philosophy*¹⁰—an essay on the population question, published about 1874, which was withdrawn from circulation, and republished by Bradlaugh and Mrs. Besant, explaining so-called Malthusian methods of preventing conception—was the beginning of these practices being taken up and adopted by a certain number of the

educated classes. At first these methods, it may be safely said, were exclusively used by these classes, but as they became more known the directions for their use gradually percolated through the various social grades, until at the present moment very few newly married women exist who do not know all about them. The proof of this is that in a friendly society giving "lying-in benefits" from 1866 to 1880, the proportion of lying-in claims rose slowly from 217 to 247 per 1,000, and then steadily declined from 1881 to 1904, when it reached only 117 per 1,000 members.

These methods are the result, in my opinion, of the increased indulgence and ever-growing luxury which existed before the war, and because those who wanted to keep in the rush of continued social engagements could only do so by curtailing expenses, and one way was to avoid having children, with the necessary expenditure attached to them. In others, to whom money was not perhaps of such immediate value, the duties and responsibilities of motherhood were too exacting to allow of thorough social enjoyment, and therefore the chance of conception must be avoided by every means in their power, with the result that if even only one child was born into the world it was a mistake, and if by chance these matters were not immediately discussed after marriage and a child was born, every care was taken that a second must be prevented.

When Malthus advanced his thesis that the constant tendency of all living beings is to increase faster than the food supply, he pointed out the immediate checks to population, as epidemics, war, pestilence, famine, etc., but that the preventive checks were moral restraint and vice—the former peculiar to man through the use of reason, the latter full of injury to general and domestic happiness. He defines moral restraint as restraint from or postponement of marriage from prudential reasons, with conduct strictly moral while unmarried; and he considered that the period of celibacy should be extended until there is a prospect of being able to feed and maintain children.

The whole question, apart from morals, is a very difficult one, for we know that if certain marriages did not take place with the distinct understanding that the birth of children was to be prevented, only on account of financial reasons, these marriages would not occur at all, and those concerned would suffer much unhappiness. But we have only to consider what is best from a physiological point of view, and what in the end leads to healthy men and women for the State.

Undoubtedly the origin of the whole trouble is the cost of living at the present day—a cost which does not seem likely to decrease for some time; and this is a matter which could only be dealt with by the State.

Many years ago, when life was much more simple than at present, there was not the same desire on the part of those marrying to prevent the advent of a family, and the more children a woman had the prouder she became of the number. Now, however, it is all changed, and the main point apparently for a couple about to be married, is how they can be most comfortable on their income. In fact, the source of the decline of the birth rate is not increased poverty but the propagation of the "gospel of comfort," which has become the ethical standard for all civilized nations. Therefore the presumption is that the fall in the birth rate is due to conditions within the control of the people.

The following is an interesting table (compiled by Dr. Jacques Bertillon) as to the annual birth rate per 1,000 between the ages of 15 and 50 in four cities:

Classification:	Paris.	Berlin.	Vienna.	London.
Very poor quarters	104	157	200	197
Poor quarters	95	129	164	140
Comfortable quarters	72	114	155	107
Very comfortable quarters	65	96	153	107
Rich quarters	53	63	167	87
Very rich quarters	34	47	71	63
Average	80	102	153	109

The table on the correlation of the birth rate with the social and physical characteristics of the population for the year 1901 shows that the wives in the districts of less prosperity and culture have the largest families, and the morally and

socially lowest classes in the community are those which are reproducing themselves with the greatest rapidity.¹²

The relation of income to birth rate has been studied in several European countries. The result of this investigation shows that the birth rate falls as income increases, and national statistics point in the same direction.

The conclusion is obvious, that as the decline seems almost universal, and people do not change their morality in a large number of different countries at a given time without some definite cause, the determining one—a strong economic fact—is the "gospel of comfort."

Now, the test of fertility in a woman is the rapidity with which she conceives; ideal fertility would imply immediate conception after marriage, perfectly normal pregnancy, labour, and, again, rapid conception during the whole of the sexual period of life. This, however, rarely occurs. Making allowances for sources of error tending to diminish the average amount of fertility, ten is about the average fertility of fertile marriage during the whole of the child-bearing period of life.¹³

This shows how important the study of sterility becomes with reference to the State, for we know that on an average one marriage in ten is sterile, which means that during the whole of the child-bearing period there is a loss to the State of 1,000 children for every 100 marriages.

From the point of view of advantage to the State there is another matter which deserves attention, and that is the vitality of the children born. This is of the highest importance, because a woman who habitually brings into the world children who survive only a few hours or days, or are still born, is of no service to the State, and therefore infant mortality under one year calls for more attention than hitherto been paid to it. Important reforms, however, take a long time to mature, and we must hope that with the Ministry of Health many beneficial changes will be brought about with reference to child life.

It is difficult to state accurately how many infant deaths or what proportion of them, are due to congenital causes. Herbert M. Rich found that in 6,866 deaths under one year of age 23.2 per cent. were due to malformations, congenital debility, and premature birth. According to Henoch,¹⁴ every 1,000 children born, 200 die in the first year of life. Dr. Amand-Roult¹⁵ estimates that there are four times as many abortions as stillbirths—that is, 2.2 stillbirths to 8.8 abortions to 100 live births—which means that in England and Wales 76,000 fertilized ova die annually before they are born.

Priestley said there is one abortion for every three or four full-time deliveries, and that from three to six out of every ten women abort at least once during their married life.¹⁶

There is another matter which has a serious bearing on the diminishing population, and that is the attempts to procure abortion, either criminally or by the use of drugs. With regard to the latter, the information given by Dr. Thomas Oliver as to the use of diachylon by pregnant women in the North of England is important. It is evident from the statistics already prepared that contraceptives or limitation of the occasions of sexual intercourse, which are extensively employed, must account for the fall in the birth rate, and this cannot be attributed to any possible decline of natural fertility. With reference, however, to both these matters, it is quite obvious that it would be impossible to collect sufficiently accurate data to be of any real value; but it may here be remarked, it has been stated that in a large Continental town, where there was strong neo-Malthusian open propaganda, one-third of the pregnancies were aborted.¹⁷

There is a factor which is of the highest importance with reference to the State—that is, the amount of nutriment available. Abundance of nutriment increases the number of births, and this applies to the whole of the animal world, although we know that this does not imply excessive feeding which has an injurious effect on breeding. It is known that the great influence of nutrition upon fertility by the result of famine, which leads to decrease of the population. It may be said, generally speaking, it is believed that the effect of comparative freedom from anxiety leads to the increase of fertility, and that the reverse conditions are followed by a diminution in childbirth.

It will be interesting for those who compare the statistics of to-day with those compiled, say, twenty years hence, after the establishment of the Ministry of Health. It will be essential for that department to see that the poorer classes are provided with sanitary and well-ventilated houses, and that those in existence not entitled to come under the

ription shall be swept away. This means that factory and those doing regular daily work in mills and warces will be able to be in a healthy atmosphere during the time they are at home. Everything which is done to improve the general health of girls, and to keep it at the highest possible, will ensure that, when they marry, they will have the best chance of conceiving, and, if the husband be fit, of bringing into the world healthy offspring.

It cannot be too strongly emphasized that, from the point of view of the State, it is not conception alone which counts, the bringing forth of healthy children who are capable of living and becoming useful members of the community; as we are on this subject, I may say that whilst there is nothing to prevent men and women marrying whilst in different health, according to our present laws, I am fully of opinion that every man and woman should, before marriage, be compelled to be medically examined. This at once would be the means, in many cases, of discovering evidence of syphilis, gonorrhoea, tubercle, or of any other, or of obtaining such information as would lead to suspicion of the existence of one or other of these diseases. Gonorrhoea may be said to be the commonest cause of sterility and relative sterility in women, probably 50 per cent. of all cases. With such a percentage this disease must be an important bearing with reference to the State.

The influence of gonorrhoea and syphilis on the birth rate is asserted in different ways: gonorrhoea lessens the birth rate by preventing conception; syphilis influences the birth rate and infantile mortality in a different and much more serious way. We know from the figures of Hoehsinger¹⁸ and Eeder and Jeans¹⁹ that about 40 per cent. of pregnancies in syphilitic women end in abortions or stillbirths, and of the infants born alive about one-quarter die. Dr. Amand Routh considers that about 25 per cent. of abortions and stillbirths are due to syphilis in city populations, and in rural districts the proportion is probably from 15 to 20 per cent.²⁰

Elsewhere I have called attention to the influence of the cocoon on the female pelvic organs,²¹ and when I wrote that paper there were over 71,000 cases of gonorrhoea in the British Army alone. Therefore the prophylaxis should be carried closely, and ought to be dealt with from a practical point of view. It ought to be our aim to stamp out this disease, and although in the light of our present knowledge its eradication is at present beyond us, we shall do most good by encouraging in every possible way any means to the end in view, and notification comes first of all.

As we are now certain that every case is a potential means of only spreading the disease, which may be mild or severe, but of practically crippling a healthy woman for life, all as possible rendering her sterile, it is our duty to leave no stone unturned to accomplish our object. Doubtless there are many arguments against compulsory notification of syphilis, gonorrhoea, but we know that, owing to these diseases, loss to the State is enormous. If we are to have healthy men and women, individual susceptibilities ought to be swept away, and the State should have control of the treatment. The public will soon be educated to the fact that State registration can be done with the greatest privacy, and that no one need be concerned with any name but the doctor entering it. The officials have only to deal with figures. Therefore, all communications will be treated as confidential State secrets, open for statistics to the Registrar-General alone.

The extreme importance of registration is in order to know when a patient is pronounced to be cured. My strong opinion is that when once the name has been entered by a doctor the individual should be obliged to consider himself or herself under treatment until medically certified as well, and that he should be penalized if it can be proved that intercourse taken place before receiving a certificate of health or of being entered in the registry as cured. By no other means can this scourge be eradicated.

Moreover, I am strongly of opinion that no marriage should be considered legal until both the man and the woman about it have been passed as fit for the responsibility of the possible procreation of children. This may seem a harsh condition at the present time, but the people would be educated to the knowledge that the State would not recognize a marriage between individuals unfit for matrimony. Parents, therefore, would know that, before allowing their girl to become engaged, they must be sure that the man wished to marry was healthy in all respects. In this unsuitable marriages from a State point of view could be avoided. This means that a medical certificate must be issued by each, but considering that every man and woman

desirous of obtaining life assurance must be examined medically, no hardship is entailed.²² Not only would this preclude the possibility, so far as our knowledge would permit, of having any sort of venereal disease, but it would safeguard the race from other affections.

Doubtless at first such an idea may be resented, but when on reflection it is considered that it is only to ensure as far as possible healthy children for our country, there is no weighty argument to be advanced against it. As it is of the utmost importance to the State to have children born into the world vigorous and healthy, it is to be hoped that the time will come when no marriage will be allowed to take place unless sanctioned from a medical point of view.

At the present moment we have no law to prevent any marriage, whatever be the circumstances or religion, in any country. If in certain cases there is strong evidence on either side to lead to the opinion that only infants likely to be mentally deficient, tuberculous, or otherwise diseased, can result from the union, then there ought to be no hesitation in asking for the consent of the man or woman, or both, to be sterilized, which would in no way prevent them living an ordinary married life. This would avoid the unhappiness likely to follow an order forbidding a marriage undesirable from every point of view to the State, and would prevent the legalizing of such unions as can never benefit the State.

No laws can ever prevent the advent of illegitimate children, but if legislation were to be passed with reference to marriage, men and women of education would not face the social consequence of running counter to the law, especially as marriage would only be denied in those cases in which sterilization was not agreed to.

It would be difficult to estimate the loss in numbers of idiots and other undesirable individuals which such legislation would produce, but such a lessened number of births would surely be received with satisfaction by those who are anxious to control the birth rate.

War will go on as long as human passions remain; pestilence may arise at any time, as witness the terrible scourge of influenza which affected practically the whole world, carrying away thousands—the deaths in England and Wales, to say nothing of shattered health, amounting to 112,329, only comparable to the mortality of the terrible epidemic of cholera in 1849; and famine must occasionally rear its head, as in the awful visitations of Russia and India. Therefore there need be no fear that there will be any dangerous increase in the population.

It is for the political economist to point out in what manner the population is to be fed, and for statesmen to follow any advice which is sound; but, from our point of view, we have to do our best to secure the birth of vigorous children, and everything in our power to make arrangements for their upbringing in such healthy surroundings as will give them the best chance of survival.

Whilst we have no power to interfere with the private lives of individuals, I consider that our profession ought to let it be known that contraceptives and anything which interferes with physiological laws cannot have our approval, and I think that, as regards the Obstetric Section of the Royal Society of Medicine, the expression of opinion of those who took part in the discussion following the paper of Dr. Arthur Giles in May last on sterility makes this clear.

I may say that I am fully aware that such a proposal as mine of a State marriage certificate means an Act of Parliament, and probably much opposition. But is there any commendable reason why we should bring into the world so many idiots to be supported by the State or otherwise, especially when the country is taxed almost beyond its capacity for paying, and when we know that there are means at our disposal to prevent their advent?

Dr. Stansfield says that heredity is one of the great factors in the production of our C3 population, and the trend of modern civilization, by its Poor Law system, and by its treatment of the unfit during childhood, tends to foster the growth of this class. The care given to physically and mentally unfit children may reduce the degree of unfitness, but if their improvement is such as to enable them to escape incarceration under the Mental Deficiency Act, they are turned out mental, moral, and physical weaklings, to return to an environment which was associated with the development of their unfitness.²³

According to the seventh annual report of the Board of

* It is not suggested that medical examination should exceed that for ordinary life assurance, for which the family physician can give a certificate.

Control there were over 12,000 registered mental defectives, including criminal and non-criminal.

Certainly my suggestion is more humane than that of Plato, who, whilst not being opposed to marriages, wished that the offspring of the least worthy should not be reared; or of Aristotle, who was in favour of allowing children in excess of those required to die from exposure, and that all deformed children should not be permitted to live.

In conclusion, I may say first, that, as the mortality amongst illegitimate children is so great, it would be an advantage if an effort were made to save some of their lives, and if philanthropic arrangements could be inaugurated for bringing them up in healthy surroundings, so that they might eventually become of service to the State.

Secondly, that looking to the amount of sterility, and the enormous loss of life caused respectively by gonorrhoea and syphilis, it is urgently desirable that notification of these diseases should be rendered compulsory.

Thirdly, that, as I have pointed out, we have a distinct fall in the birth rate; that by the widespread adoption of contraceptives, which from a physiological point of view cannot be approved, but which we are certain will be ever increasingly used, we must not expect an average of more than two births from each marriage—possibly only one; that, as we know from a most conservative estimate there must be at least four children per marriage amongst families who can produce children, allowing for infantile mortality, those who never marry, and those who are unfit to produce children, we cannot anticipate a real increase in the population.²⁷ It follows, therefore, that our country is faced in the future with the problem of race suicide.

And lastly, should my suggestion of the granting of a State certificate of marriage be adopted, we should have the satisfaction of knowing that in future our profession would be the means of helping to compensate for loss of numbers by ensuring for the State the advent of healthy children—the best and surest evidence of a virile race.

THE DIGESTIBILITY OF BACTERIA.

BY

C. E. DUKES, O.B.E., M.D., D.P.H.,

BACTERIOLOGICAL LABORATORY, UNIVERSITY COLLEGE HOSPITAL
MEDICAL SCHOOL.

ALTHOUGH nitrogenous substances form the basis of bacterial cells, yet bacteria are not digested by powerful proteolytic ferments, and are capable of living and multiplying in a solution which would split up those proteins of which, by chemical analysis, bacteria have been shown to be composed. That this resistant faculty is not dependent on the fact of life is demonstrated by the experience that bacteria are also not digested when killed by weak antiseptics or at low temperatures. Owing to this property bacteria are enabled to continue their existence when surrounded by the digestive juices of the intestinal canal, and also continue to thrive in a culture medium into which enzymes have been excreted by other bacteria.

Kantorowicz¹ noted that after heating at 70° C. Gram-negative bacilli are less resistant to digestion than Gram-positive bacilli, and he assumed the presence of an intracellular antiprotease which holds the proteolytic activity in check. Kruse² attributed differences in survival after heating to differences in permeability of the organisms. Jobling and Peterson³ are of the opinion that bacteria resist digestion because of the lipoids with which they are surrounded, and that this resistance is proportional to the content of unsaturated lipoids.

The following experiments were undertaken for the purpose of studying the conditions under which bacteria resist digestion, and under what conditions this protective property can be destroyed. The first stage of enzyme action is considered to be an adsorption of the enzyme on to the free surface of the substrate. The question as to whether or not bacteria are capable of adsorbing ferments was therefore first studied.

Adsorption Experiments.

It is well known that bacteria are capable of adsorbing both opsonins and agglutinins from the serum, but this action is specific and cannot be regarded as an example of simple adsorption. Porter⁴ claims that membranes such as collodion sacs and egg-white films are capable not only of adsorbing but also of inactivating ferments, and suggests that living bacteria may protect themselves by the same neutralizing process.

Technique.

To test for adsorption a technique similar to that used in the agglutination saturation test was devised—namely, a dilute solution of the ferment was saturated with a heavy dose of bacteria, the tube centrifuged to deposit the bacterial mass, and the titre of the supernatant fluid compared with a similar ferment solution which had not received a saturating dose of bacteria. The ferment employed was trypsin (Burroughs, Wellcome and Co.'s "injectio trypsin" and Fairchild's "zymine"), and the titre tested by the digestion of 4 per cent. gelatin by Sorensen's method.⁵ In this the degree of digestion is measured by the quantity of amino-acids formed. These are estimated from the carboxyl group liberated after treatment with 33 per cent. formalin solution, the acidity being determined by titration with N/100 NaOH. The twenty-four hours' bacterial growth from thirty large agar plates was washed off with saline and centrifuged, and again washed with saline. The bacterial deposit was suspended in as little fluid as possible, usually about 50 c.cm.

Thirty tubes were employed in each test. The first ten were used for determining the strength of the trypsin solution, and into each of them was placed 1 c.cm. of saline, followed by graded quantities of trypsin solution varying from 0.1 in the first tube to 1.0 c.cm. in the tenth tube, the total quantity of fluid in each tube being made up to 2 c.cm. with saline. The second series of ten tubes contained the same ingredients except that instead of 1 c.cm. of saline there was first placed in each tube 1 c.cm. of bacterial suspension. In the third series of ten tubes the trypsin acted on a suspension of fibrin or animal charcoal, which was used as a control to show the effect of adsorption. In some experiments the bacteria were left in contact with the ferment for only a few minutes, in others for as long as twenty-four hours. But the period of contact made no difference, nor did it matter whether the mixtures were left at room temperature or in the incubator. All the thirty tubes were centrifuged at high speed until the supernatant fluid was clear. One c.cm. of the supernatant fluid from each tube was now transferred to a sterile test tube containing 10 c.cm. of 4 per cent. gelatin, and placed in the water bath at 37° C. After thorough mixing a sample of 5 c.cm. was withdrawn from each tube and tested as above described. Digestion of the remainder was allowed to proceed, and another sample of 5 c.cm. gelatin removed after a definite period of time. The quantity of N/100 NaOH required to neutralize the first sample subtracted from the amount required to neutralize the second sample indicated the extent of digestion of the gelatin. A comparison of the figure obtained in each tube of the second and third series of tubes with that obtained in the first series of ten tubes indicated the loss sustained by the ferment after having been saturated by bacteria or fibrin or charcoal.

Several organisms were used, but the majority of the tests were made with *B. typhosus*, *B. coli*, and *sarcinae*. It was found that living bacteria did not adsorb trypsin at all, a result which is shown diagrammatically in Fig. 1, in which the quantities of trypsin employed are plotted against the titration readings. On the other hand, charcoal and fibrin adsorbed trypsin readily, the degree of adsorption being more pronounced in dilute than in stronger solutions. A series of experiments were made to see if organisms which had been in contact with specific immune serum could adsorb ferments. Typhoid bacilli, sensitized with antityphoid serum, were used, but were found to have no effect on ferment titre. Bacterial suspensions were made of organisms which had been boiled, autoclaved, killed with antiseptics, and others defatted with acetone, alcohol, and ether. In no case was any adsorption process observed when the supernatant fluid was tested on gelatin. It was, however, found in the case of bacteria extracted with acetone, or after boiling or autoclaving, that the trypsin after saturation, although showing no adsorption when tested on gelatin, yet showed a reduction in titre when tested on a substrate of acetone-extracted or boiled bacteria.

As will be pointed out subsequently, treatment with acetone and the process of heating renders bacteria capable of digestion by trypsin. It would seem, therefore, that adsorption does take place when bacteria are so treated as to be rendered

digestible by trypsin, but to demonstrate this adsorption it is necessary to employ digestible bacteria as substrate. This may be due to the fact that another fraction of the trypsin enzyme is required to attack the digestible bacteria from that required for gelatin. There are many who hold that trypsin is a compound of many proteolytic ferments.

It is perfectly clear, however, that bacteria in their natural condition do not adsorb the ferments with which they are in contact as do other foreign particles.

FIG. 1.—Showing effect on titre of trypsin by saturating with bacteria and charcoal.

Digestion Experiments.

Although unaltered bacteria are resistant to trypsin, yet by the application of certain chemical substances or physical processes this normal resistance may be overcome. To study the digestion of bacteria directly various methods may be employed. The simplest is to look for clearing in a turbid suspension, but this procedure is open to the objection that it does not distinguish between bacteriolysis and proteolysis, two very different processes; nor does it lend itself to exact measurement. In the experiments about to be described bacteria were digested with trypsin, and the degree of digestion estimated by the same method as that already described under adsorption experiments—namely, the rate of formation of amino-acids as the result of the digestion of the bacterial mass.

A large mass of bacteria was obtained from agar plates, the organisms centrifuged and washed and distributed in sterile tubes. Trypsin was added, a sample of the mixture removed for immediate testing, and the remainder examined after definite periods in the water bath at 37° C. Living bacteria and bacteria killed by heating for an hour at 60° C. showed no digestion whatsoever.

Effect of Higher Temperatures.—As a result of being autoclaved at 115° C. for twenty minutes all the organisms experimented with were found to be rendered capable of digestion by trypsin. Boiling for ten minutes had very little effect on the Gram-positive cocci, but the Gram-negative bacilli, *B. typhosus*, *B. coli*, and *B. pyocyaneus* were rendered easily digestible by this process. A temperature of 70° C. applied for thirty minutes was sufficient to destroy the ferment resistance of *B. coli* and *B. typhosus*.

Effect of Treatment with Acids and Alkalis.—To test the effect of alkalis and acids on bacterial antitrypsin NaOH or HCl was added to the bacterial suspension distributed in test tubes, so as to make the resultant fluids of a strength of N 2, N 4, N 8, N 16, N 32, N 64. After five minutes' contact the acid solutions were neutralized with alkali and vice versa. The tubes were allowed to stand for half an hour and then tested with trypsin. It was found that this short contact with acid had no effect on bacterial antitrypsin, whereas alkali of higher concentrations than N 10 com-

pletely destroyed the resistance of bacteria, and concentrations as low as N 30 alkali resulted in some digestion. In such experiments it is necessary to allow the alkali only to act for a short period of time because, although clearing of the solution occurs when bacteria remain in contact for a long time with weak solutions of alkali, alkali albumin is slowly formed, and this substance is not digested by trypsin. Not all bacteria behave alike when treated with alkaline solutions. Gram-positive organisms are much more resistant to alkalis than are Gram-negative.

Effect of Treatment with Fat Solvents.—Contact with acetone, alcohol, chloroform, or ether completely destroys the resistance of bacteria to trypsin. The bacterial mass may be extracted with the fat solvent in a Soxhlet apparatus, or the same result may be achieved by precipitation from an aqueous solution and allowing the bacteria to remain in contact with the fat solvent for twenty-four hours. Amino-acids are rapidly produced by digesting the dried bacterial mass with trypsin. The rate of digestion of such organisms is shown in Fig. 2.

Effect of Drying.—The bacterial suspension obtained from washing off the growth from sixty agar plates was dried *in vacuo*, and the dry powder obtained resuspended in saline and digested with trypsin. Partial proteolysis was found to take place. Similar experiments were made in which, after drying, the powder was divided into two equal parts. One half was digested with trypsin without further treatment; the other half was treated with absolute alcohol at -14° C. and dry ether at -8° C. for the purpose of extracting the fats without coagulating the protein. This was the method adopted by Teale and Bach⁶ in their work on serum antitrypsin. This extraction of the fats made no difference to the extent of the subsequent digestion.

Effect of Sensitization, etc.—A number of experiments were now undertaken for the purpose of determining how it is that bacteria are split up in the body, either when injected subcutaneously or intravenously. Since the results were all negative it will be sufficient to record them briefly. Bacteria sensitized with specific agglutinating serum were not split up by proteolytic ferments. Washed agglutinated *B. coli* treated with fresh complement were not digested by trypsin. Acetone-extracted typhoid bacilli were agglutinated with autityphoid serum, and after centrifuging the supernatant fluid was tested and it was found that practically all the agglutinin had been removed. Such sensitized acetone-

FIG. 2.—Showing digestion of *B. typhosus* by trypsin.

extracted typhoid bacilli were not digested any more rapidly than unsensitized acetone-extracted typhoid bacilli. In a quantity of sterile inflammatory lymph was obtained by injecting 5 c.c. peptone (5 per cent.) into the peritoneum of a rabbit and after eight hours washing out the peritoneal cavity. The leucocytes were removed by centrifuging. Prolonged contact with this sterile inflammatory exudate made no difference to the digestibility of the organisms employed.

Discussion.

The facts above recorded are of interest from two points of view. In the first place it is seen that those agencies which most readily destroy the bacterial antitrypsin are all fat solvents—namely, alcohol, acetone, ether, chloroform, and

alkalis. The lipoids contained by bacteria, because of their effect on surface tension, are probably concentrated round the periphery of the bacterial cells, and form a protective covering to the organism. This fatty envelope protects them from proteolytic ferments, but once this has been removed active proteolysis takes place. High temperatures and drying cause a redistribution of the lipid-protein complex, and thus, for physical reasons, disturb the protective mechanism. Therefore the antitryptic property of bacteria depends on totally different factors from the antitrypsin of egg white and blood serum.

Teale and Bach⁷ showed that the antitryptic power of egg white was due to the presence of a non-diffusible protein substance which is not affected in the dry state by treatment with lipid solvents. The same observers showed that the antitrypsin of blood serum was not dependent on the lipoids present.

Although lipid solvents appear to destroy the antitrypsin of blood serum, they do this by coagulating the proteins. Drying had no effect on the antitrypsin of blood serum, nor was it destroyed by lipid solvents when precautions were taken to prevent protein coagulation.

The greater resistance of Gram-positive bacilli to lipid solvents and heat is also capable of explanation on the basis of the physical dispersion of the lipoids.

Eisenberg⁸ found that staphylococci became Gram-negative after extraction with ether and that *B. coli* could be made Gram-positive on treatment with lecithin. Benians⁹ observed that crushed Gram-positive organisms are promptly decolorized, and concluded that the condition of the cell wall is the factor determining resistance to Gram's stain.

In Gram-positive organisms it would appear, therefore, that the lipoids are more intimately bound to the protein of the bacterial cell, thus rendering them more resistant to lipid solvents.

In the second place, it is important to note that exposure to specific agglutinating serum or inflammatory lymph does alter the protective mechanism of bacteria against proteolytic ferments. It is claimed by Jobling and Peterson¹⁰ that bacteria treated with immune serum and complement are so altered as to be made more digestible by trypsin. They state later that bacteria treated with an excess of immune serum and complement become more resistant to proteolysis. In my experiments with *B. typhosus*, *B. coli*, and *B. pyocyaneus* it was not found possible to render these bacteria more digestible by trypsin through sensitization and complement action, although many attempts were made increasing and decreasing the sensitization and varying quantity of complement.

Conclusions.

1. Bacteria do not adsorb proteolytic ferments.
2. The protein of bacteria is protected from the action of proteolytic ferments by the lipid envelope with which they are surrounded. The agencies which destroy this protective mechanism act by disturbing the lipid distribution.
3. The antibodies present in immune serum do not in any way render bacteria more digestible by trypsin.

THE third International Neurological Congress will be held at the Salpêtrière Hospital, Paris, on June 2nd and 3rd.

THE City of Paris has authorized an expenditure of 2,500,000 francs for the purchase of radium to be used in the public hospitals for the treatment of cancer.

THE seventh French Congress of Medical Jurisprudence will be held in Paris from May 29th to 31st under the presidency of Dr. Thibierge, when the following subjects will be discussed: (1) Laboratories of criminal anthropology and psychiatry departments in Belgian prisons, introduced by Professor Héger-Gilbert and Dr. Vervaeck of Brussels. (2) The spectroscope in medical jurisprudence, introduced by Professor Zanger of Zurich and Dr. de Laet of Brussels. (3) Bone and joint tuberculosis and workmen's accidents, introduced by Dr. Robireau. Further information can be obtained from Professor Étienne Martin, 10, Rue du Plat, Lyons.

SLIPPING RIB.

BY

R. DAVIES-COLLEY, C.M.G., M.Ch., F.R.C.S.,
SURGEON, GUY'S HOSPITAL.

Abnormal mobility of the lower intercostal joints, causing painful symptoms, is probably not a rare condition, and it is curious that it should receive no mention in the modern textbooks of surgery—at least, I have failed to discover any reference to it in the numerous volumes that I have consulted. It is for this reason that I venture to report the following two cases which have come under my observation during the past year.

Slipping rib, as it may be called, is a trivial enough complaint in itself, but it gives rise to the most irksome symptoms, and my two patients were quite incapacitated by the excruciating pain which followed any attempts to do manual work. The pain is described as of a sharp, stabbing nature, giving place after a few moments to a dull ache, which lasts for a considerable time, and may, indeed, persist throughout the day, only disappearing after the night's rest. In its position at the costal margin it resembles that due to so many deeper lesions, both of the abdomen and the thorax, that I think it is quite likely that many cases occur in which such an apparently unimportant cause as a movable rib cartilage is unsuspected, and the diagnosis is missed. It was so in one of my cases, but the difficulty here was partly due to the fact that the patient, a woman, was known to have had definite abdominal disease in the past, and to the natural tendency to attribute subsequent symptoms to this disease: still, had I been acquainted before with slipping rib as a cause of abdominal pain I think I might have arrived at a correct diagnosis somewhat sooner than I did.

The treatment is simple, and consists in resection of the loose terminal portion of the rib cartilage. In both of my two cases this was followed by immediate and lasting relief of the symptoms.

CASE I.

A single woman, aged 42, employed as a domestic servant, was admitted into Guy's Hospital in September, 1921, for right-sided subcostal pain. This had first troubled her four years before, when she fell and bruised her side, and from that time it had been present more or less constantly, being most severe when she walked much or attempted to do heavy work. Recently any effort to use her right arm had brought on such severe pain that she was quite unable to work at all, and she said that when she lifted anything heavy one of her ribs seemed to jump out of place, and that frequently a painful swelling appeared at the lower margin of the ribs. This exact description was not elicited during the earlier stages of her illness, and the diagnosis was rendered less easy by the fact that in 1918 the appendix had been removed for a basal-celled carcinoma, which led to the suspicion that her pain was due to post-operative adhesions.

In August, 1920, when I first saw her with Dr. E. P. Poulton, we decided to explore the abdomen, but at the operation the stump of the appendix was found to be healthy, and the only abnormality discovered was prolapse of the caecum and ascending colon. I performed colopexy, but this naturally enough failed to relieve the symptoms, and it was only when, a year later, she volunteered the information about the slipping rib that the real cause of her pain became apparent. It was now obvious on palpation that the tip of the tenth rib cartilage could be freely moved upwards in front of the ninth, and that this movement produced the pain of which she had for so long been complaining. Removal of the terminal three inches of the rib cartilage effected a complete cure.

CASE II.

A girl, aged 17, complained of sudden acute pain in the left side whenever she bent forward or attempted to lift anything heavy. She stated that one of her ribs had been "out of place" for some months, and on examination it was clear that the tip of the tenth left costal cartilage slipped over the lower border of the ninth rib and jutted forward beneath the skin when she flexed her body. This slipping movement of the rib was accompanied by an acute twinge of pain, which left a dull ache under the rib margin for several minutes after the rib had fallen back into place. In this case, too, removal of the terminal portion of the cartilage was followed by complete relief of the symptoms.

Very definite conclusions cannot be drawn from two cases, but it is noteworthy that both of the patients were of the female sex, and that one gave a definite history of an injury as the starting point of her symptoms. In both the pain was referred to the exact position of the affected rib, the undue mobility of which could easily be demonstrated, and in both the symptoms tended to increase as time went on.

THE RESTRICTION OF INFLUENZA EPIDEMICS IN SCHOOLS BY THE USE OF "LOCAL" PROPHYLACTIC VACCINES.

BY

A. I. SIMEY, M.D.CANTAB., M.R.C.P.,

MEDICAL OFFICER TO RUGBY SCHOOL AND PHYSICIAN TO THE HOSPITAL OF ST. CROSS, RUGBY;

AND

JOHN W. H. EYRE, M.D.DUNELM., F.R.S.EDIN.,

PROFESSOR OF BACTERIOLOGY IN THE UNIVERSITY OF LONDON, AND BACTERIOLOGIST TO GUY'S HOSPITAL.

In a recent communication one of us (A. I. S.) described and discussed in general terms the catarrhal complex which so frequently attacks in epidemic form aggregations of adolescents such as are found in all public schools, and which causes the loss of so many school hours. In this communication we wish to refer to a particular outbreak of this character, and the means adopted to control and limit its spread.

During the summer term of 1920 an epidemic of febrile disease of severe influenzoid type occurred at Rugby School. Out of a total of nearly 600 boys 260 were attacked, causing the loss of about 5,000 school days to the patients themselves, as well as interfering with the work, games, and social life of those who escaped. Many of the boys were seriously ill, and suffered from manifold complications such as those described in the paper already referred to.

It originated probably from one or two boys who were sent back to school in a catarrhal condition, not technically "ill," but probably carriers of the micro-organisms which caused this outbreak; and it spread rapidly, first by houses and then by forms, until most of the susceptible succumbed.

It is not our intention to describe this epidemic but rather the subsequent train of events, in the hope that certain definite points may be established as to the cause and prophylaxis of this serious infliction, which disturbs the health of our boarding schools more than any other single factor.

During the following Advent term (1920) only 40 to 50 cases, mild in type, occurred, doubtless because the immunity of the school was high, such immunity lasting probably three to six months in average cases.

As it seemed more than probable that another outbreak was to be expected in the following Lent term of 1921, a circular was sent to parents asking them to have their boys inoculated during the Christmas holidays with suitable doses of vaccine, no special brand being specified or advised. This request was complied with in the case of only 123 out of about 570 boarders; the remaining 450 came back uninoculated and susceptible. Trouble soon began, and the infection spread so rapidly that it was thought advisable to attempt to limit its incidence by inoculating all those who had not been so treated in the holidays—if they had not already succumbed. To this end nearly every boy who had not been vaccinated at home or contracted the disease was inoculated with a stock vaccine prepared from those strains of micro-organisms that had been used in the

prophylactic inoculations carried out among the New Zealand Expeditionary Force during 1918-19,* and which had the following composition:

Dose No. 1.				
Pneumococcus	50 million.
Micrococcus catarrhalis	25 "
Streptococcus	10 "
Bacillus pneumoniae	10 "
Bacillus influenzae	10 "
Staphylococcus aureus	200 "

In view of the urgency of the situation no exhaustive bacteriological examination of this epidemic was possible, but ten recent cases of the acute and subacute types, which had been admitted into the sanatorium on February 10th, 11th, and 12th, 1921, were selected for examination. The throats and nostrils were swabbed and cultures instituted upon blood agar from these swabbings. After incubation the resulting cultures showed that in four of the acute cases the *Bacillus influenzae* of Pfeiffer was the predominant organism, and it

was also present in three of the remaining six acute and subacute cases. The organisms in the remaining cases comprised *Bacillus septus*, *Micrococcus catarrhalis*, *Staphylococcus pyogenes aureus*, *Staphylococcus pyogenes albus* (haemolytic type), *Streptococcus lanceolatus* (pneumococcus), and *Streptococcus pyogenes longus*. This last-mentioned organism being represented by two distinct types, *haemolyticus* and *viridans*. All the different strains of each of the above-noted bacteria were isolated in pure culture.

From the material thus obtained a special "local" vaccine was prepared, and the vaccine was polyvalent in the sense that all the strains available of each of these organisms were utilized in the vaccine. Strains from other sources were also incorporated in the vaccine whenever necessary, so that ten strains of each species were present, this polyvalency being of special importance in our opinion in re-

spect of the influenza bacillus itself. In addition, strains of the *Bacillus pneumoniae* were included as a precautionary measure, although this organism had not been actually demonstrated in any of the Rugby cases.

The actual composition of the vaccine employed for the second dose, which was injected fourteen days after the first dose, was as follows:

Dose No. 2.				
Pneumococcus	100 million.
Micrococcus catarrhalis	75 "
Streptococcus	50 "
Pneumobacillus	100 "
Bacillus septus	100 "
Bacillus influenzae	50 "

The dosage of the various components of this prophylactic vaccine will no doubt be regarded as exceedingly small when contrasted with those recommended by the Ministry of Health in connexion with the antiscarlatina vaccine supplied by that body. It is, however, dependent upon the selection of strains and the distance from the human host of the particular cultures furnishing the antigen, in accordance with principles already laid down, and need not, therefore, be discussed here.

alkalis. The lipoids contained by bacteria, because of their effect on surface tension, are probably concentrated round the periphery of the bacterial cells, and form a protective covering to the organism. This fatty envelope protects them from proteolytic ferments, but once this has been removed active proteolysis takes place. High temperatures and drying cause a redistribution of the lipid-protein complex, and thus, for physical reasons, disturb the protective mechanism. Therefore the antitryptic property of bacteria depends on totally different factors from the antitrypsin of egg white and blood serum.

Teale and Bach⁷ showed that the antitryptic power of egg white was due to the presence of a non-diffusible protein substance which is not affected in the dry state by treatment with lipid solvents. The same observers showed that the antitrypsin of blood serum was not dependent on the lipoids present.

Although lipid solvents appear to destroy the antitrypsin of blood serum, they do this by coagulating the proteins. Drying had no effect on the antitrypsin of blood serum, nor was it destroyed by lipid solvents when precautions were taken to prevent protein coagulation.

The greater resistance of Gram-positive bacilli to lipid solvents and heat is also capable of explanation on the basis of the physical dispersion of the lipoids.

Eisenberg⁸ found that staphylococci became Gram-negative after extraction with ether and that *B. coli* could be made Gram-positive on treatment with lecithin. Benians⁹ observed that crushed Gram-positive organisms are promptly decolorized, and concluded that the condition of the cell wall is the factor determining resistance to Gram's stain.

In Gram-positive organisms it would appear, therefore, that the lipoids are more intimately bound to the protein of the bacterial cell, thus rendering them more resistant to lipid solvents.

In the second place, it is important to note that exposure to specific agglutinating serum or inflammatory lymph does not alter the protective mechanism of bacteria against proteolytic ferments. It is claimed by Jobling and Peterson¹⁰ that bacteria treated with immune serum and complement are so altered as to be made more digestible by trypsin. They state later that bacteria treated with an excess of immune serum and complement become more resistant to proteolysis. In my experiments with *B. typhosus*, *B. coli*, and *B. pyocyaneus* it was not found possible to render these organisms more digestible by trypsin through sensitization and complement action, although many attempts were made by increasing and decreasing the sensitization and varying the quantity of complement.

Conclusions.

1. Bacteria do not adsorb proteolytic ferments.
2. The protein of bacteria is protected from the action of proteolytic ferments by the lipoidal envelope with which they are surrounded. The agencies which destroy this protective mechanism act by disturbing the lipid distribution.
3. The antibodies present in immune serum do not in any way render bacteria more digestible by trypsin.

SLIPPING RIB.

BY

R. DAVIES COLLEY, C.M.G., M.Ch., F.R.C.S.,
SURGEON, GUY'S HOSPITAL.

ABNORMAL mobility of the lower intercostal joints, causing painful symptoms, is probably not a rare condition, and it is curious that it should receive no mention in the modern textbooks of surgery—at least, I have failed to discover any reference to it in the numerous volumes that I have consulted. It is for this reason that I venture to report the following two cases which have come under my observation during the past year.

Slipping rib, as it may be called, is a trivial enough complaint in itself, but it gives rise to the most irksome symptoms, and my two patients were quite incapacitated by the excruciating pain which followed any attempts to do manual work. The pain is described as of a sharp, stabbing nature, giving place after a few moments to a dull ache, which lasts for a considerable time, and may, indeed, persist throughout the day, only disappearing after the night's rest. In its position at the costal margin it resembles that due to so many deeper lesions, both of the abdomen and the thorax, that I think it is quite likely that many cases occur in which such an apparently unimportant cause as a movable rib cartilage is unsuspected, and the diagnosis is missed. It was so in one of my cases, but the difficulty here was partly due to the fact that the patient, a woman, was known to have had definite abdominal disease in the past, and to the natural tendency to attribute subsequent symptoms to this disease: still, had I been acquainted before with slipping rib as a cause of abdominal pain I think I might have arrived at a correct diagnosis somewhat sooner than I did.

The treatment is simple, and consists in resection of the loose terminal portion of the rib cartilage. In both of my two cases this was followed by immediate and lasting relief of the symptoms.

CASE I.

A single woman, aged 42, employed as a domestic servant, was admitted into Guy's Hospital in September, 1921, for right-sided subcostal pain. This had first troubled her four years before, when she fell and bruised her side, and from that time it had been present more or less constantly, being most severe when she walked unevenly or attempted to do heavy work. Recently any effort to use her right arm had brought on such severe pain that she was quite unable to work at all, and she said that when she lifted anything heavy one of her ribs seemed to jump out of place, and that frequently a painful swelling appeared at the lower margin of the ribs. This exact description was not elicited during the earlier stages of her illness, and the diagnosis was rendered less easy by the fact that in 1918 the appendix had been removed for a basal-celled carcinoma, which led to the suspicion that her pain was due to post-operative adhesions.

In August, 1920, when I first saw her with Dr. E. P. Poulton, we decided to explore the abdomen, but at the operation the stump of the appendix was found to be healthy, and the only abnormality discovered was prolapse of the caecum and ascending colon. I performed colopexy, but this naturally enough failed to relieve the symptoms, and it was only when, a year later, she volunteered the information about the slipping rib that the real cause of her pain became apparent. It was now obvious on palpation that the tip of the tenth rib cartilage could be freely moved upwards in front of the ninth, and that this movement produced the pain of which she had for so long been complaining. Removal of the terminal three inches of the rib cartilage effected a complete cure.

CASE II.

A girl, aged 17, complained of sudden acute pain in the left side whenever she bent forward or attempted to lift anything heavy. She stated that one of her ribs had been "out of place" for some months, and on examination it was clear that the tip of the tenth left costal cartilage slipped over the lower border of the ninth rib and jotted forward beneath the skin when she flexed her body. This slipping movement of the rib was accompanied by an acute twinge of pain, which left a dull ache under the rib margin for several minutes after the rib had fallen back into place. In this case, too, removal of the terminal portion of the cartilage was followed by complete relief of the symptoms.

Very definite conclusions cannot be drawn from two cases, but it is noteworthy that both of the patients were of the female sex, and that one gave a definite history of an injury as the starting point of her symptoms. In both the pain was referred to the exact position of the affected rib, the undue mobility of which could be demonstrated, and in both the symptoms tended to

THE RESTRICTION OF INFLUENZA EPIDEMICS IN SCHOOLS BY THE USE OF "LOCAL" PROPHYLACTIC VACCINES.

BY

A. I. SINEY, M.D.CANTAB., M.R.C.P.,

MEDICAL OFFICER TO RUGBY SCHOOL AND PHYSICIAN TO THE HOSPITAL OF ST. CROSS, RUGBY;

AND

JOHN W. H. EYRE, M.D.DUXELM., F.R.S. EDIN.,

PROFESSOR OF BACTERIOLOGY IN THE UNIVERSITY OF LONDON, AND BACTERIOLOGIST TO GUY'S HOSPITAL.

IN a recent communication one of us (A. I. S.) described and discussed in general terms the catarrhal complex which so frequently attacks in epidemic form aggregations of adolescents such as are found in all public schools, and which causes the loss of so many school hours. In this communication we wish to refer to a particular outbreak of this character, and the means adopted to control and limit its spread.

During the summer term of 1920 an epidemic of febrile disease of severe influenzoid type occurred at Rugby School. Out of a total of nearly 600 boys 260 were attacked, causing the loss of about 5,000 school days to the patients themselves, as well as interfering with the work, games, and social life of those who escaped. Many of the boys were seriously ill, and suffered from manifold complications such as those described in the paper already referred to.

It originated probably from one or two boys who were sent back to school in a catarrhal condition, not technically "ill," but probably carriers of the micro-organisms which caused this outbreak; and it spread rapidly, first by houses and then by forms, until most of the susceptible succumbed.

It is not our intention to describe this epidemic but rather the subsequent train of events, in the hope that certain definite points may be established as to the cause and prophylaxis of this serious affliction, which disturbs the health of our boarding schools more than any other single factor.

During the following Advent term (1920) only 40 to 50 cases, mild in type, occurred, doubtless because the immunity of the school was high, such immunity lasting probably three to six months in average cases.

As it seemed more than probable that another outbreak was to be expected in the following Lent term of 1921, a circular was sent to parents asking them to have their boys inoculated during the Christmas holidays with suitable doses of vaccine, no special brand being specified or advised. This request was complied with in the case of only 123 out of about 570 boarders; the remaining 450 came back uninoculated and susceptible. Trouble soon began, and the infection spread so rapidly that it was thought advisable to attempt to limit its incidence by inoculating all those who had not been so treated in the holidays—if they had not already succumbed. To this end nearly every boy who had not been vaccinated at home or contracted the disease was inoculated with a stock vaccine prepared from those strains of micro-organisms that had been used in the

prophylactic inoculations carried out among the New Zealand Expeditionary Force during 1918-19, and which had the following composition:

Dose No. 1.

<i>Pneumococcus</i>	50 million.
<i>Micrococcus catarrhalis</i>	25 "
<i>Streptococcus</i>	10 "
<i>Bacillus pneumoniae</i>	50 "
<i>Bacillus influenzae</i>	10 "
<i>Staphylococcus aureus</i>	200 "

In view of the urgency of the situation no exhaustive bacteriological examination of this epidemic was possible, but ten recent cases of the acute and subacute types, which had been admitted into the sanatorium on February 10th, 11th, and 12th, 1921, were selected for examination. The throats and nostrils were swabbed and cultures instituted upon blood agar from these swabbings. After incubation the resulting cultures showed that in four of the acute cases the *Bacillus influenzae* of Pfeiffer was the predominating organism, and it

was also present in three of the remaining six acute and subacute cases. The organisms in the remaining cases comprised *Bacillus septus*, *Micrococcus catarrhalis*, *Staphylococcus pyogenes aureus*, *Staphylococcus pyogenes albus* (haemolytic type), *Streptococcus lanceolatus* (pneumococcus), and *Streptococcus pyogenes longus*, this last-mentioned organism being represented by two distinct types, *haemolyticus* and *viridans*. All the different strains of each of the above-noted bacteria were isolated in pure culture.

From the material thus obtained a special "local" vaccine was prepared, and the vaccine was polyvalent in the sense that all the strains available of each of these organisms were utilized in the vaccine. Strains from other sources were also incorporated in the vaccine whenever necessary, so that ten strains of each species were present, this polyvalency being of special importance in our opinion in respect of the influenza bacillus itself.

In addition, strains of the *Bacillus pneumoniae* were included as a precautionary measure, although this organism had not been actually demonstrated in any of the Rugby cases.

The actual composition of the vaccine employed for the second dose, which was injected fourteen days after the first dose, was as follows:

Dose No. 2.

<i>Pneumococcus</i>	100 million.
<i>Micrococcus catarrhalis</i>	75 "
<i>Streptococcus</i>	50 "
<i>Pneumobacillus</i>	100 "
<i>Bacillus septus</i>	100 "
<i>Bacillus influenzae</i>	30 "

The dosage of the various components of this prophylactic vaccine will no doubt be regarded as exceedingly small when contrasted with those recommended by the Ministry of Health in connexion with the antiscarlatina vaccine supplied by that body. It is, however, dependent upon the selection of strains and the distance from the human host of the particular cultures furnishing the antigen, in accordance with principles already laid down, and need not, therefore, be discussed here.

Curves showing the progress of the "influenza" epidemic. Lent Term, 1921. Black continuous line = cases admitted to sanatorium. Dotted line = cases ill in "houses."

The accompanying diagram shows the daily case incidence throughout this epidemic, under the two headings: those admitted to the sanatorium (black continuous line), and those ill in their respective boarding houses (dotted line); so that to obtain the number of cases under treatment on any given day it is necessary to add together the sum total of both groups.

The general results may be briefly summarized in tabular form, and the following statistics, showing the percentage of those who succumbed, more or less speak for themselves:

(a) Those who received both vaccines at school	...	7.3
(b) Those who were inoculated at home	...	41.0
(c) Those who were not inoculated at all	...	81.0
(d) Those who received only the initial stock vaccine at school	...	84.0

The number of individuals comprised in these four different classes totalled 565. Class (a) comprised 232 individuals, of whom 19 became infected. Class (b) comprised 123 individuals, and yielded 52 cases. Class (c) contained 160 boys, and no less than 130 cases came under treatment. Only 50 boys fell into category (d); out of these 42 succumbed. These figures show a total of 243 cases infected.

Grouping classes (a), (b), and (d) together we arrive at a total of 405 boys who received one or more inoculations, from whom the combined number of cases totalled 113—in other words, an incidence of 27.9 per cent., as opposed to 81 per cent. among the uninoculated.

By way of comment it must be recognized that Class (a) probably includes many of the naturally least susceptible cases, whereas Class (c), on the other hand, consists almost entirely of those who, being very susceptible, contracted the disease before the first inoculation was given at school. Class (d) represents the well-known fact that susceptibility to infection is temporarily increased by the first of two such inoculations, and this constitutes the "factor of danger" when preventive inoculations have to be undertaken in the presence of an epidemic. In the case of Class (b) various vaccines were used—one, two, or three doses being administered according to the varying home circumstances.

During the following summer holidays parents were again requested to have their boys inoculated before their return to school with the special "local" vaccine referred to. In some instances this was done, but in many instances the second dose was given after the boys' return to school, and again many received no prophylactic treatment. The total number of cases that occurred during the subsequent Advent term of 1921 was 21 only. Of these, 8 occurred in boys who had received prophylactic inoculations, whilst the remaining 13 occurred amongst the uninoculated.

We are indebted to W. W. Vanghan, Esq., M.V.O., Headmaster of Rugby School, for permission to record these results and figures.

ALUMINIUM THROAT SWABS.

BY

LACHLAN GRANT, M.D., C.M., D.P.H. EDIN.,
F.R.F.P.S. GLASG., J.P.

BACTERIOLOGIST, DISTRICT COMMITTEES, ARGILL COUNTY COUNCIL;
MEDICAL OFFICER, FEVER HOSPITAL, LORN.

A few years ago¹ Dr. William Murdie and the writer drew attention to an improved throat swab made from aluminium wire. Since then inquiries regarding it have come in to this laboratory from time to time, and its further extensive use by us and others have confirmed the claims made for it.

The ordinary types of swabs now in use have several serious drawbacks and disadvantages, and a more efficient kind of instrument seems to be called for. Those made of copper, iron, steel, or thin nickel wire are somewhat easily tarnished, and if left lying in a climate the least damp are very liable to become discoloured and unsuitable for use. Copper and nickel are apt to develop verdigris or a green colour from the soluble copper and nickel salts, and brown discoloration is also likely to happen with those made of iron, which develop "rust" or ferric oxide. Such swabs, after being in use or laid aside for a time, acquire an unattractive and unhygienic appearance, and are not the sort of thing to ask a patient to admit to his throat. The pledget of sterile wool is also likely to be stained, and as the soluble copper and

nickel salts are germicidal, these may more or less invalidate the bacteriological diagnosis.

By the use of the aluminium wire these and other undesirable accompaniments are obviated. It is easily moulded to shape and yet is sufficiently rigid for swabbing purposes, and it keeps bright and clean. No matter how often used, or even if kept for a considerable time, the aluminium swab never has the soiled or discoloured appearance of those made from other metals. It stands boiling well and is easy to clean and redress. Again, aluminium contains in its composition no harmful bactericidal elements.

The addition of the safety ring (see illustration) avoids the holding of the cork and gives a more complete control over the movements of the swab, thus minimizing the risk of introducing organisms other than the patient's own. In the ordinary one, as usually made, there is always the risk of the

metal slipping from the cork, which is avoided by this firmer type. Aluminium being so light, the cost of the wire is very small. The best thickness to use is that known on the aluminium wire gauge as E 14 S.W.G. As there is no fear of "rusting" or "greening," the cotton-wool pledget may, if desired, be held under the running tap before swabbing the patient's throat, thus ensuring a good sample of the infected secretion, and also retarding the drying effects of transmission through the post, etc.

The throat swab is a useful item in the practitioner's armamentarium, and the aluminium wire swab holder, well made, will be found helpful in the diagnosis, prognosis, and treatment of some of the diseases met with in everyday practice. We know it is practically impossible, without a bacteriological examination, to make sure whether a patient who complains of a sore throat is suffering from diphtheria, "mixed" throat infection, Vincent's angina, follicular tonsillitis, or an infection by the *Trypanema pallidum*. Complete tests thoroughly carried out from start to finish are invaluable in speedily determining or in eliminating certain or all of these diseases and so removing the anxiety attached to an undecided clinical diagnosis. In attaining this, a hygienic, safe, clean, light, and easily handled swab is an important adjunct.

Of course, whatever kind is used, it is important to take the necessary precautions to avoid its contamination. The pledget of wool for conveying the suspected material is necessarily small, and in gently rubbing the infected surface care must be used that the wool on its introduction or withdrawal does not get soaked with saliva or other oral secretions. One has also to remember that the use of antiseptic gargles prior to use may interfere with the results to be obtained from the cultural tests when the swab reaches the laboratory. It may be further mentioned that the aluminium swab can also be made longer for special uses, as, for example, in the taking of material from uterine infections.

I am indebted to Mr. I. H. MacIver for the sketch illustrating the points described.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

INFLUENZA WITH EXTREME HYPERPYREXIA.

PUBLICATION of the following case of influenza accompanied by extreme hyperpyrexia (temperature 114° F.) may be of interest, especially as some mention of it has been made in the lay press:

On January 15th I was called to see a maid who had been exposed to influenzal infection on January 9th and developed the usual symptoms of malaise, headache, and slight fever, January 12th. On the morning of the 15th she felt worse, with excruciating pain in the back and a temperature of 103° at 9 o'clock. I examined her at noon. She was very pale, the skin moist but not excessively hot, the pulse of good volume, and regular, the rate 120. The heart was normal. Great tenderness was present in the left lumbar region. She had vomited several times, felt faint, and had not passed urine for nearly twenty-four hours. The abdomen was soft except for faecal masses, and there was no evidence of a distended bladder. When I took the temperature the thermometer registered 112° in the axilla. She

was too delirious to take it in the mouth. Thinking there must be a mistake I shook the thermometer down and took it again, with the same result. I then used two other thermometers with the same result, after excluding any other source of error, such as a hot-water bottle. I held the thermometer in the axilla and the girl kept still during the process. She was at once sponged with cold water (85°), and the temperature rapidly fell to 100°. After a small rise at 2 p.m. it fell to 99°.

Dr. Carey Coombs examined the case with me. The maid had a few spots on the chest, intense pain in the back, and transient rashes on the arms and legs. The heart was not enlarged, but the recurrent faintness made me fear a fatal collapse at any time. Nativelle's digitalin, gr. 1/240, was given two-hourly, and the patient encouraged to take brandy and milk with soda. The intense pain in the back continued, but the temperature remained down till 7 p.m., when it rose to 103°. Sponging was recommenced, but the temperature reached 108.6° before it was brought down to normal. The patient passed an extremely restless night with frequent vomiting. Next morning a turpentine enema was given, with small result of almost stony hard stools, the patient passing urine at the same time. At 2 p.m. the temperature rose rapidly to 114°, the patient looking extremely ill, and a fatal result appeared imminent; but sponging at once brought down the temperature (which had been carefully confirmed by secondary readings on other thermometers). This was again taken in the axilla. The pulse was regular, the rate 120, but poorer in volume and tension

Reports of Societies.

RELAPSING FEVER IN INDIA.

The problem of the epidemiology of relapsing fever, as it occurs in India, was the subject of a paper read on February 16th before the Royal Society of Tropical Medicine and Hygiene by Major F. W. Cragg, I.M.S., of the Central Research Institute, Kasauli, whose observations were largely based on personal investigation and experiment. He drew attention to the fact that overcrowding and dirt were almost universal from long-established custom amongst the peasant populations of India, and by favouring the spread of pediculosis presented many difficulties in dealing satisfactorily with the question of relapsing fever. Moreover, the harborage of lice, as a normal condition, in Major Cragg's opinion, robbed this important factor in the transmission of the disease of much of its significance. Loose infestation among the warmly clad races of Europe and Asia was highest in winter, but with the scantily clothed natives of Northern India, where the disease was endemic, relapsing fever reached its highest during the hottest months of the year. Its distribution, most marked in the United Provinces and endemic in the Punjab, was by no means general, for it did not prevail in Bengal, Assam, and the southern part of India, largely rice-growing districts, whereas its greatest prevalence was found in the wheat-growing tracts of Northern India, coinciding with the ripening of the spring crop. In contrast to other parts of the world typhus and relapsing fever were not associated in India, and Major Cragg was puzzled to explain the apparent absence of typhus. The origin of the epidemic of 1917 was attributable to some common cause affecting numberless foci in the northern districts where the disease had previously been prevalent. By means of a "relapsing fever index," derived from the study of seasonal prevalence and special age incidence, the disease was defined as occurring more heavily in certain districts than others, with a duration of epidemic conditions amounting to about two years. The outbreaks, in Major Cragg's opinion, could not be explained by changes in the conditions of the people at the time of onset, such as exceptional poverty or movements of the population. An underlying cause, therefore, had to be sought for in some additional and hitherto unrecognized factor. Towards the solution of this problem and to confirm the work of French investigators, the aid of experiment was brought to bear. Emulsified preparations of lice, collected from relapsing fever cases, were injected into five monkeys without producing any obvious illness. However, injections of 2 c.c.m. of infective blood, containing the spirochaetes, into a fresh monkey proved more successful, and the animal became definitely ill; 10 c.c.m. of its heart blood withdrawn under an anaesthetic provided material for further experiment; 5 c.c.m. were injected into another monkey subcutaneously and 1 c.c.m. into each of the five monkeys previously inoculated with emulsified lice. All showed rises of temperature, two having definite two-day fever, and in three spirochaetes were found in film preparations of their blood. Dissection of lice at intervals of two to seventeen days after being fed on cases of relapsing fever and on an infected monkey resulted in the finding of spirochaetes only in those fed on the seventh to the eleventh days.

Major Cragg, having succeeded in confirming the results of previous workers, which established the louse as the vector of Indian relapsing fever, turned his attention to the bionomics of the insect host. He made a number of observations in the habits and activities of the louse under conditions comparable with those in an Indian dwelling and amid the climatic changes of temperature and humidity occurring from month to month on the Indian plains. His experiments showed that, corresponding with rises in atmospheric temperature, and as it approximated to that of the human body at the end of March and in April, so the temperature and humidity of the average Indian louse provided optimum conditions for the insect. Its movements and productivity became accentuated, but as the season advanced and hot weather set in lice tended to die off and become scarce. The seasonal activities of the insect, therefore, closely corresponded with the period of greatest prevalence of relapsing fever. Explanation of the epidemic in 1917, a year of abnormal climatic conditions in India, was to be found in the fact that the months of April, May, and June experienced temperatures below the normal and high atmospheric humidity, and therefore conditions favourable to the prolonged life of the louse.

than previously. In view of the sickness the digitalin was withdrawn and camphor in olive oil was given intramuscularly in its place. The pain in the back was decreasing and vomiting thenceforth became steadily less. At 8 p.m. the temperature again went up to 112°, but as soon as the face and arms were sponged, and before their effect could have been produced, the temperature fell to 107° and to 99° an hour later.

So far no antipyretic drugs had been given for fear of their action on the heart. Cryogenin 0.5 gram was then commenced four-hourly. The patient passed a good night and appeared much better in the morning. A turpentine and olive oil enema had a large result, and from this point on the patient made uninterrupted progress. On January 27th the patient commenced normal menstruation, which lasted four to five days. A week later, when it had been arranged for her to go to a convalescent home, she twice walked in her sleep on February 1st and 3rd—going downstairs to the rooms of the ladies of the house and asking irrelevant questions about household duties. On being taken back to her room she at once continued apparently normal sleep, instead of waking, as so many somnambulists do on being returned to bed. These nocturnal peregrinations may have been caused by excitement in the preceding day, in spite of every effort to avoid such a condition. The girl is aged 22, one of a family of seventeen, not robust, of a markedly hysterical temperament, and distinctly lacking in mental balance and restraint, though not sufficiently so to be classed as mentally deficient.

That the girl recovered I attribute to the fact that the high temperatures were of short duration, that cardiac tonics were given before the heart showed signs of collapse, and that throughout I had the help of two invaluable nurses who acted with commendable promptitude. As to the accuracy of the temperatures, I certainly doubted, but after every possible source of error had been eliminated I was compelled to accept what I had previously regarded as the impossible.

In consequence the normal period of its activity was much extended, and with it there occurred a great increase in prevalence of relapsing fever; attaining to a formidable epidemic in the early months of 1918, when optimum conditions returned. Similar abnormal climatic conditions recorded in 1877, Major Cragg argued, would explain the severe epidemic which developed in that year, and was the subject of Vandyck Carter's classic report. The low temperatures of the first six months in 1877 were ascribed to heavy snowfall in the winter, and in 1917 to great rainfall in the spring. In each of these two years there was a failure of rains in the following autumn, and with it famine occurred. Therefore, famine and relapsing fever appeared attributable in some measure to a common cause and did not stand to each other in the relationship of cause and effect. The value of this conclusion, it was observed, pointed to the importance of appreciating the effect of climate on the prevalence of the disease. In the event of an unusually cool summer a study of the monthly vital statistics for a rise in the death rate of young adults should lead to local investigation and examination of blood films, and thus to possible timely discovery of the disease before the epidemic became serious.

The high incidence among young adults, in Major Cragg's opinion, was perhaps due to their habit of crushing the louse between the finger and thumb nail, thus setting free the spirochaetes, which may penetrate the soft tissues under the nail; whilst sex incidence was probably explained by the greater liability of males to skin abrasions, whereby the spirochaetes might obtain access to the blood stream.

REMEDIAL EXERCISES IN SCOLIOSIS.

A discussion on "Remedial exercises as applied to scoliosis" took place at a meeting of the Section of Orthopaedics of the Royal Society of Medicine on March 7th, when Mr. E. LAMING EVANS presided over a very large attendance, including many lady instructors in gymnastic exercises in schools and clinics. It was noteworthy that throughout the discussion the scoliotic subject was referred to in the feminine gender, although one speaker said that the worst cases of curvature he had ever seen were in some Eton boys of a generation ago, when the youth who did not of his own initiative enter into sports was apt to be neglected.

Mr. McCRAE AITKEN, in opening, described the two main uses of exercises in scoliosis as being (1) to increase mobility by stretching tight structures, and (2) to establish good positions by teaching the patient to use her muscles properly. No surgeon or gymnast ever cured a case of scoliosis, though a patient might cure herself under a gymnast's guidance. If the deformity was at all rigid, so that the patient could not by voluntary effort improve her position, the first stage of treatment must be a series of active movements designed to loosen the joints and secure more mobility. If the patient could voluntarily correct herself and could hold the correction it was time to begin re-education. The patient must understand the nature of the deformity, and by the use of mirrors get accustomed to see herself corrected. She must be shown how, by taking certain positions, the deformity could be modified; her attention must then be directed to her own muscle sensations on assuming the correct position, and following upon this certain exercises must be employed, of which thigh movements, influencing the lumbar region, were the most useful, and the patient should be taught, having gained the muscle sense, to apply these movements to the ordinary occasions of her everyday life; without such application no amount of exercise was of any real use.

Mr. E. B. CLAYTON divided scoliosis into three groups postural, borderline, and fixed. In postural cases, while there was no fixed curve, the patients required individual attention until they learned to stand and sit properly. Young children were very likely to relapse into the scoliotic posture, no matter on how many occasions they might visit the hospital clinic; therefore adequate treatment necessitated re-examination at intervals during school life. In borderline cases, where there was a slightly fixed scoliosis, he found the trouble liable to recur whenever treatment was stopped, so that here it seemed necessary to go on inspecting the children's backs until they reached adult years. In the severe cases, with fixed curvature, not much improvement could be obtained in posture, but the back could be strengthened and the general health improved. Therefore he advocated remedial exercises in scoliosis (1) to relieve backache, (2) to

improve the general health, chest development, and posture, and (3) to prevent the fixed curve from increasing, even though it could not be eradicated.

Dr. FLORENCE BARRIE LAMBERT said that in orthopaedic surgery the British nation was pre-eminent, but as regards remedial, gymnastic exercises we had scarcely advanced during the last twenty-five years. The same exercises were still being taught as were taught a generation ago in Sweden, based on the knowledge of orthopaedics then available. How many orthopaedic surgeons and physiotherapists believed nowadays in the so-called pressure exercises? Yet the teaching of these exercises took up very nearly half the time occupied in teaching remedial gymnastics. She classified scoliosis into postural, structural, and intermediate conditions. The postural was due to imperfect balance and, as a rule, was better treated by educational gymnastics given daily in schools, with proper attention to hygiene and general physique, than by remedial exercises. As for the structural condition, nobody advocated that the fixed curve should be treated by remedial exercises only. There remained the intermediate class, and here the speaker was uncertain whether the right kind of exercises were being given. Some agreement ought to be reached on this question, and she suggested that a committee of orthopaedic surgeons and physiotherapists should be formed to inquire into the present syllabus of the Chartered Society of Massage and Medical Gymnastics, because she thought that there was at present a great waste of children's time through useless and ill-directed treatment. The adult who was given ineffective treatment had his remedy, but not so the child, especially when the treatment was provided by the local authority. She wondered at times at the psychology of some of the people who were working in clinics—whether they were not the victims of self-hypnotism. Usually no notes were taken, yet they spoke of wonderful results, while all that the visitor could see was a mass of derelict cripples. A large percentage of the children treated in clinics should not be there. At one clinic which she had officially inspected a well-known orthopaedic surgeon, on taking it over, ruled out 60 per cent. of the children as not suitable cases for the treatment. She urged that surgeons should not advise the sending of children for remedial treatment which was not part of a hospital orthopaedic scheme.

Mr. PAUL BERNARD ROTH described a system of exercises which had been introduced by his grandfather and modified by his father and himself. It consisted in putting the patient in the best possible position and exercising her in it. The standard exercises were twelve in number, and were given daily—exercises twice a week were almost useless—for from one to three months, and the re-education of the muscle sense of the patient was carried out coincidentally with the strengthening of the muscles. The exercises were: (1) Deep breathing, lying; (2) arm movements, lying; (3) thighs opposite bar, standing; (4) leg circling, lying; (5) head movements, lying; (6) astride, sitting; (7) arm circling, lying; (8) leg circling forwards, lying; (9) half forwards, lying, heels fixed; (10) arm flexion, lying; knees bent, and head extension, lying; (11) long sitting, heels fixed; (12) standing back to ladder, also hanging back to ladder. He believed that the system of exercises as taught in England to-day and carried out by masseurs was based on a wrong principle, and should be given up, and that in its place there should be such a simple set of exercises as he had described, carried out under the direct daily personal supervision of the surgeon, who must himself take part in the treatment.

Dr. R. T. TIMBERG stood by his old faith in Swedish gymnastics, whose foundations had stood the test of time for the treatment of spinal curvature. He admitted that the varying aspects of a complex problem like scoliosis must be taken into consideration, and he was not such a slavish follower of the Swedish system as to claim its sufficiency for all forms of scoliosis; but he believed it to be the most judicious scheme yet devised, and the one which adapted itself to the greatest number of conditions. He thought that correcting jackets were less enthusiastically advocated in this country than was the case ten years ago, but the use of such jackets rendered exercises more, not less, necessary.

Dr. CARL WESTMAN referred to the extraordinary variance of opinion recorded in the textbooks with regard to certain mechanical factors in spinal curvature, and urged that much more research work was required to find out exactly how curvatures began. This subject had not been sufficiently studied, so far as the beginnings of the condition were concerned, in infancy. The electrical department might be of

assistance in discovering which muscles should be re-educated and which muscles taught to relax.

Dr. J. B. MENSELL said that very few of them could affirm that they were satisfied with the present treatment of scoliosis; at the same time there was a good deal to be said for existing methods. Although many of the attempts to alter curvatures or to correct deformities might lamentably fail, there were certain pleas to be urged for the treatment commonly given, even for that form of it which was generally deemed—namely, manual correction of deformity. There must be something in such manual correction. The Americans were not a people of ill-balanced mind, yet vast numbers of them had their pet osteopath, to whom they went at intervals to be “limbered up.” It was not the deformity to which people objected, but the symptoms. No possessor of a flat foot—which might be regarded as analogous to scoliosis—objected to the flat foot itself, but to the rigidity and the symptoms which it provoked. By manipulation of the foot, pain and discomfort could be relieved, and it was the same with the manipulative measures for the relief of the back symptoms and the maintenance of mobility. He insisted, as other speakers had done, that it was the patient who cured herself, not the physiotherapist who cured her; and in this connexion he suggested that elaborate instrumentation was a disadvantage, because it gave the patient the notion that cure would not depend upon her own efforts. The simpler the appliances, therefore, and the greater the challenge to the patient's own exertion, the better.

Mr. R. C. ELISLIE said that he always classified his cases into postural and structural. He asked himself in the presence of any curve whether he could produce that curve in a normal child of the same age by manipulating the spine; if he could, it was obviously a postural condition, which could be completely corrected, and if he could not, there was a structural abnormality. His examination of children in secondary schools showed 17 or 18 per cent. of them to have postural curves, and this proportion was lower than figures given in literature; some Continental investigations showed a proportion as high as 25 per cent. Was individual remedial treatment to be advocated for all of these? He believed that in these cases the call was for physical education, not for remedial exercises. As for the structural curve, the thing of first importance was to find what produced it, and to catch their cases early. It was necessary to weed out from remedial gymnastics the things that were useless, or that were liable to be misunderstood and therefore wrongly applied, and to add to the treatment all the lessons which could be gained from general educational gymnastics.

Mr. T. H. OPENSHAW also referred to the inclusion of two distinct conditions under the name of scoliosis: one in which the spine was quite movable, and the other in which the bones had become altered and the curvature fixed. In Germany and Sweden one never saw such fearful cases of scoliosis as were presented among East End children in London, so that the treatment which was quite proper and efficient for scoliosis as defined by Swedish writers was not efficient in these severe cases. Many bad cases of scoliosis were due to pathological softening of the bone or to caries, and the co-operation of the orthopaedic surgeon should be more constantly sought. One method of treatment in severe scoliosis which ought to be emphasized was the provision of the spinal plaster bed, which ensured—that could not be ensured in the case of any person by voluntary effort alone—that the patient would lie flat on his back throughout the night. Without this fixed support, exactly fitting the back, every person, whether his spine be normal or abnormal, would turn on his side in sleep.

After some further discussion it was agreed that an endeavour should be made to bring about a conference between the Councils of the Chartered Society of Massage and Medical Gymnastics and of the Orthopaedic Section, with a view to the possible revision of the syllabus of remedial exercises.

EXPERIMENTAL PATHOLOGY.

At a meeting of the Section of Pathology of the Royal Society of Medicine held at University College Hospital Medical School on March 7th, Professor A. E. BOYCE presiding, the first paper, read by Dr. LAZARUS-BARLOW, described further attempts at the experimental production of carcinoma in rats by means of radium. In order to lower the resistance of rats to cancer before subjecting them to radium, they were given a course of treatment by potassium, since it has been found

that patients with cancer have more potassium salts circulating in the blood and that rats have been found to be more susceptible to carcinoma after the administration of potassium. Irradiation also was carried out for the purpose of lowering the resistance. During the course of this treatment tubes of radium were introduced into the rats and certain inflammatory lesions followed, which had many resemblances to cancer. Dr. Lazarus-Barlow called attention to four changes which he regarded as possible criteria of the presence round the tube of radium: those of a neoplasm; a cystic condition of the lungs, possibly due to metastases; the permeation of the lymphatics between the muscle layers of the stomach by collections of endothelial cells; and endothelial proliferation. One or more of these signs was present in 39 out of 48 rats experimented on, but attempts at propagation of these growths by inoculation were not successful.

In the subsequent discussion, in which many members of the Section took part, some criticism was expressed of these criteria of malignancy, but Dr. Lazarus-Barlow in his reply pointed out that he was only reporting on attempts to produce malignant growths, and did not claim he had already achieved his object, but suggested that the lesions he had produced had many resemblances to malignant growths.

Dr. C. E. DICKES read a paper on adsorption of ferments by bacteria. He described experiments which were designed to ascertain whether it was possible to lower the titre of a solution of trypsin by saturating the ferment with large doses of bacteria. Charts were shown illustrating the fact that animal charcoal and powdered fibrin adsorb ferments, but it was demonstrated that bacteria even in massive quantities have no effect in lowering the ferment titre. No physical change resulting in fixation of the ferment occurred as the result of sensitizing the bacteria with specific agglutinating serum, nor did bacteria rendered digestible by the action of heat or fat solvents show any capacity for adsorbing ferments.

A paper was read by Dr. EMBERTON on work carried out in co-operation with Dr. Teale on the subject of intestinal infection. Tables were shown illustrating the fact that bacteria injected into the stomach are destroyed and do not cause infection. Organisms injected into the intestinal tract were never found at a higher level than the point where introduced. It was shown that the gastric juice is a powerful germicide, killing off bacteria in a few minutes; but if the hydrochloric acid of the stomach is neutralized then bacteria are not killed; 0.3 per cent. HCl behaves in a similar fashion. When bacteria are inoculated intravenously they are found in the blood, mouth, and intestines, but never in the stomach, unless the contents of that organ are alkaline. The conclusions to which the authors have arrived are: (1) That the gastric juice and intestinal mucous membrane are very good barriers against the passage of bacteria into the body; (2) that when bacteria are taken into the mouth they may be absorbed through the buccal and pharyngeal mucous membrane, but the exact point where absorption takes place has not been definitely established; (3) that bacteria introduced into the body by any route are always excreted into the intestinal tract.

A paper was read by Professor BOYCE on the restoration of blood volume after haemorrhage and anaesthesia, embodying experiments carried out with the collaboration of Dr. Price Jones. In unanaesthetized animals they showed that even after severe bleeding the blood volume is restored after about three hours, fluids passing back from the tissues into the blood. If, however, the animal was bled when anaesthetized by ether and urethane, then the blood volume was not restored. Attempts were made to induce the restoration of blood volume during anaesthesia by such means as tetanizing and administration of carbon dioxide, but they were not successful. It was shown that with ether alone and urethane alone the same results were obtained, and also with gas and oxygen anaesthesia, but with the latter it was not found possible to anaesthetize laboratory animals in a satisfactory manner, some degree of asphyxia always being produced. Even without bleeding the blood volume is reduced during anaesthesia, and the authors arrived at the conclusion that anaesthetics have the effect of causing a redistribution of fluids in the body, the blood becoming more concentrated and the tissues containing more fluids. Experiments were described in which the blood volume was increased by transfusion and the animal subsequently anaesthetized. The blood volume of such an animal returned to

the original level more rapidly when under an anaesthetic than when not, from which it was concluded that anaesthetics diminish the permeability of the vessels from without inwards.

STERILITY AND THE STATE.

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on March 2nd, with Professor HENRY BRIGGS, President, in the chair, Dr. R. A. GIBBONS read a paper on sterility with reference to the State, which is printed in full at p. 427. In the discussion that followed Dr. T. W. EDEN said that he was not prepared to admit that a higher birth rate was necessarily an advantage to the State. He saw no advantage in producing more babies than could be provided for by their parents or employed later in the business of the country. In the war the two countries in Europe with the highest birth rate were now in the sorriest plight of all, while the two nations with the lowest birth rate, France and England, won the war. In reply to Dr. Gibbons's fears that France was on the way to committing "race suicide," he pointed out that before the war she was economically one of the strongest nations in the world, and never had the acute crises of unemployment which occurred in England. The idea that the proposed medical examination before a marriage could be made legal filled him with amazement, and he thought it might have the effect of discouraging marriage.

Dr. AMAND ROUTH agreed almost entirely with Dr. Gibbons that the main cause of the lowered birth rate was voluntary limitation of conception, which he believed led to much harm in both potential parents. It was unnecessary, for this country had to defend its dependencies all over the world, and the need for immigration into those lands was almost illimitable. The diminishing birth rate, due to voluntary limitation, was especially amongst classes which are best able to afford it. Malthus's original plan was the postponement of marriage and abstinence for varying periods afterwards if necessary. Neo-malthusianism connoted early marriage, or no marriage, with the use of contraceptives. If limitation was necessary the doctor should decide upon its methods. Dr. Gibbons's proposals to check national sterility could only be adopted if pressure of public opinion demanded it. Health certificates before marriage, again, bristled with difficulties, especially as regards women, and might perhaps be met as an alternative by the life insurance of both partners to a marriage, the medical fee for examination to be paid by the State if need be. Voluntary sterilization of the unfit by vasectomy or salpingectomy could not yet be encouraged by the State, and compulsory sterilization, even of imbeciles under State control, was not yet possible. Confidential death certificates, which were in use in every other European country, would enable more reliable statistics of infantile deaths to be available. Stillbirths should be registered, not merely notified to a medical officer of health as now, and the cause of the deaths should be investigated by experts.

Dr. LAPHORN SMITH called attention to the overcrowding and bad housing conditions in many of our large cities and towns; an increase of population would make matters worse. There were two million women who could never marry in this country, because there were not enough men. These should go overseas, where they could meet an equal number of unmarried British men.

Dr. ARTHUR GILES said that Dr. Gibbons's paper appeared to him to be very opportune and most suitable for discussion in the Section, because those interested in State medicine did not interest themselves overmuch in questions of sterility: the general practitioner and gynaecologist were chiefly concerned in this matter. If only those who could not afford to bring up children controlled their families little could be said against it; but control was chiefly exercised by people who could well afford the care of children, and this was a real loss to the State. It was necessary to distinguish between what the State could do and what was dependent upon public opinion. The State could certainly take steps for the care of illegitimate children, and could legitimize children whose parents married after their birth. Public opinion, on the other hand, could do a great deal in other directions. A better teaching could be spread abroad showing the drawbacks of restricting childbirth. He doubted whether State regulations requiring a medical certificate before marriage would be practicable, but he thought public opinion might do much in this direction.

Decidual Reaction in an Extrauterine Adenomyoma.

Mr. C. D. LOCHRANE read a communication on a small irregular tumour in the recto-vaginal septum of a pregnant nullipara, which proved on section to be a typical adenomyoma. The cellular mantle surrounding the gland spaces showed a very extensive and complete reproduction of decidua compacta exactly similar to that seen in the uterus during normal pregnancy. The gland epithelium was chiefly of the flattened columnar type, and showed evidences of hyperplasia in places. The patient gave a previous history of painless menstruation without excessive loss, and there was no family or personal history of tubercle or gonorrhoea, but a small fibro-adenomatous polypus hung from the external os uteri. There had been temporary difficulty on defaecation, with melaena, on two occasions before pregnancy began. The specimen, he believed, was unique, as the only other reported extrauterine case showing similar appearances was not definitely circumscribed nor dissociated from the uterus as was the tumour in this case. The Müllerian theory of origin of uterine and extrauterine adenomyomata received the strongest support from the following facts: (1) Though a great number of extrauterine adenomyomata had been reported at various times, these were the only two reported in association with pregnancy, and they had shown an associated decidual reaction in the tumour in 100 per cent. of instances. (2) There was no reported case, unassociated with pregnancy, of decidual reaction in an adenomyoma wherever situated. (3) Of eight uterine cases of adenomyoma in association with pregnancy collected from the literature by Lockyer, all but two showed definite decidual reaction in the connective tissue stroma of the associated tumour, and these two were open to doubt as they did not appear to have been sectioned serially. It was probable that adenomyomata owed their inception to an antecedent inflammatory condition in the tissues of origin.

Mr. T. G. STEVENS considered the specimen a most important one, as it served as a link in the chain of evidence in support of the theory that all adenomyomata were in reality derived from the endometrium. Although a decidual reaction was occasionally seen in tissues not derived from the Müllerian duct, such as the stroma of the broad ligament, such specimens were exceedingly rare, and then only occurred in immediate relationship to a tubal pregnancy which had ruptured between the layers of the broad ligament. On the other hand, any tissue directly derived from the Müllerian duct would be expected to share in the decidual changes which normally occur in the endometrium.

GROWTH OF THE FACE IN MAN.

A JOINT paper on the growth of the human face was read before the British Society for the Study of Orthodontics last December by Sir ARTHUR KEITH and Mr. GEORGE CAMPION and discussed at its meeting on March 6th. Mr. CAMPION contributed a series of measurements showing the vertical and sagittal increase from childhood to full growth. The vertical measurements were made from nasion to submental point, with intermediate measurements, and the sagittal from the transmental line to the nasion, upper central incisor, and submental point. The number of individuals measured was thirty. Sir ARTHUR KEITH contributed a detailed comparison of immature with mature skulls, designed to show the areas where growth takes place. The interesting observation was made that in the modern Englishman the nasion moves forward and upward with growth, whereas in primitive native races and in prehistoric English skulls it moves forward or forward and downward. It was demonstrated that concurrently with growth of bone there is absorption and remodelling, as in the cutting back of the base of the anterior nasal orifice, and the absorption of the anterior surface of the malar process of the superior maxilla. Sir Arthur Keith was convinced that the modern British face was becoming longer and narrower. Increase of width was found to be largely dependent on growth at the maxillary and intermaxillary (palatal) sutures. The modern narrow-faced English skull was found to be wanting in growth at both these areas. Special attention was drawn by the authors to growth at the intermaxillary and inter-nasal sutures—a point they believed to have been hitherto overlooked. A comparison of acromegalic with normal skulls showed that the acromegalic face was enlarged by a process of true growth, the growth changes being found in the same areas and being of the same nature as those seen in normal

subjects. The authors thought that the narrow English face with the accompanying adenoid and tonsillar enlargements was the expression of an underlying pathological condition, which might result from a nutritional disturbance—perhaps a deficiency of vitamins in the dietary of youth.

The adjourned discussion brought together a large meeting of the society and visitors, including the president of the Japanese Dental Association. Professor JOHNSON asked whether a standard could be established. In answer to a question by Mr. RUSHTON, Professor KERR said he thought deflected nasal septum might be due to a failure of forward growth of the face. Mr. J. G. TURNER thought that observations on the growing dental arches showed that growth at the intermaxillary suture was of but limited extent. Much criticism was levelled at the remarks on causation of the "adenoid face," and the PRESIDENT, in summing up the debate, pointed out that the important point was that the authors of the paper had shown where and how to look for the normal factors in the growth of the human face, thus establishing a sound basis for the study of orthodontics.

In reply, Mr. CAMPION said that though the number of measurements was few they were made on individuals with entire dentitions, and Professor KERR urged that the number of different growth centres showed that there must be a co-ordinating mechanism. He added that he and Mr. Campion regarded the paper as a preliminary study and almost as showing the extent of our ignorance.

DIFFERENTIAL DIAGNOSIS OF THE EXANTHEMATA.

A DISCUSSION took place at the Medical Society of London on March 13th, Mr. JAMES BERRY presiding, on the differential diagnosis of the common exanthemata.

Dr. E. W. GOODALL, in introducing the subject, said that in certain of the communicable exanthemata the diagnosis could often be made on a single symptom—for example, the buccal exanthem of measles; but in others it was a combination of symptoms which was the deciding factor, especially in scarlet fever, enteric fever, and occasionally even in measles. Enteric fever was the only one of these diseases in which the pathologist, represented by the bacteriologist, had come to the assistance of the clinician. In typhus the pathologist had still to establish his claim, and if they were to judge by the confusion introduced into the diagnosis of diphtheria by the discovery of the Klebs-Loeffler bacillus, on account of its ubiquity and protean nature, he confessed he looked forward with no little apprehension to the bacteriologist's success in establishing the cause of scarlet fever. The eruptions of chicken-pox, small-pox, and enteric and typhus fevers were pathognomonic, and were never forged by other affections, or by one another, with such accuracy that the forgery could not be detected. But this was far from being the case with scarlet fever, measles, and rubella, the rashes of which were not pathognomonic. The rash of scarlet fever was an erythema, more or less punctate, evenly spread over the trunk and limbs, but avoiding face, forehead, scalp, palms, and soles. Similar rashes might occur as the second stage of rubella or measles, as the prodromal rash of measles and chicken-pox, as the result of an enema or a drug, and in the disease known as recurrent scarlatiniform erythema. Rubella was the most difficult condition to distinguish from scarlet fever. He had known, in measles, a diagnosis of scarlet fever to be superimposed because the discrete, macular erythema of measles had become merged into a confluent, punctate erythema, an event by no means unusual. He had known also a scarlatiniform rash which had been produced by quinine and belladonna to be mistaken for scarlet fever. In nearly 600 instances of serum rashes occurring at the North-Western Hospital, the rash could only be described as scarlatiniform in 7 cases, and in 6 of these it was strictly limited to the skin around the site of injection. Great importance seemed to be attached to peeling as evidence of an attack of scarlet fever, but for his own part he declined to admit that a case was scarlet fever unless there was satisfactory evidence that peeling had been preceded by an illness of which sore throat and rash at least had been symptoms. Any erythema or dermatitis might be followed by peeling which was quite indistinguishable from that of scarlet fever. Pinhole desquamation, held by some to be characteristic of scarlet fever, might occur after measles, rubella, urticaria, serum

rashes, and other febrile erythemas. There was no single symptom which was characteristic of scarlet fever; the diagnosis must be made on the combination and sequence of signs and symptoms. Morbilliform eruptions did not give so much trouble as scarlatiniform. Fortunately in measles, if seen early, the buccal exanthem known as Koplik's spots was a pathognomonic sign. In measles also there was usually a febrile period with catarrhal symptoms for three or four days before the rash. Serum rashes were frequently morbilliform; but while with these there might be a good deal of constitutional disturbance, there were none of the signs of measles beyond the rash and pyrexia. The differentiation between small-pox and chicken-pox must depend upon the distribution of the lesions and their individual character. The eruption of small-pox affected the face and scalp, the distal parts of the extremities rather than the proximal, and the back of the trunk more than the front. As for enteric and typhus fevers, in his experience the most valuable clinical sign in these diseases was the eruption, which in each disease was pathognomonic. Dr. Goodall concluded by showing epidiascope illustrations of the various conditions.

Dr. W. McC. WANKLYN spoke on the diagnosis of small-pox, which he said had a national as well as a clinical and professional interest, because this country, unlike every other in Europe, elected to keep the dreaded scourge at bay not so much by protecting all the inhabitants by vaccination as by reliance upon the instant recognition of small-pox as soon as it appeared. Four-fifths of the population of England and Wales were liable to take small-pox if freely exposed; only eight out of thirty-six millions of people were protected by vaccination. The late Dr. Ricketts placed the diagnosis of small-pox upon a scientific basis by his demonstration of the rash distribution, making it a simple matter, in the great majority of cases, to differentiate between chicken-pox and small-pox. Dr. Ricketts had pointed out that the rash of small-pox favoured the areas of skin which were specially liable to irritation, such as the hands and face, the extensor rather than the flexor surfaces, and so on. Looking back over something like 15,000 cases of small-pox and suspected small-pox, the speaker was able emphatically to bear out Dr. Ricketts's contention. In very many cases complete certainty in diagnosis could be arrived at by the simple plan of counting the spots and seeing whether they fell in with the usual distribution of the rash of small-pox or of chicken-pox. The rash of chicken-pox was centripetal, that of small-pox was centrifugal. The method of making an actual count of the spots in mild cases and of plotting them on a diagram form was used with much success in a recent outbreak in the North of England. Dr. Butterworth's report on the outbreak in Lancashire showed that the prompt diagnosis of cases, aided by this means, was one of the factors which operated in speedily bringing it to an end.

Dr. A. F. CAMERON remarked that scarlet fever was one of the most difficult of infectious diseases to diagnose, and small-pox one of the easiest. In small-pox the most constant and least variable sign was the rash distribution. This had the advantage of being a sign which in no way depended on the patient's testimony or the previous history of the case. Small-pox was capable of producing three kinds of eruption: an erythema, a purpura, and a focal lesion, essentially a vesicle. He could not remember seeing an erythema in small-pox which resembled the rash of scarlet fever or measles in any particular except its colour. He believed that the hæmorrhagic small-pox was only an exaggeration of the inherent purpuric tendency of the disease.

Sir JOHN BROADBENT said that it was by no means easy to distinguish a mild case of scarlet fever from a case of rubella, or a severe case of rubella from scarlet fever. It was important to examine the whole body and note the distribution of the rash. The throat in scarlet fever would generally show a little more congestion than in rubella, and the tongue was characteristic as a rule, though it must be admitted that there were cases in which it was almost impossible to make a certain diagnosis as between the two conditions. Another perplexing problem was the scarlatiniform rash in diphtheria. One must not trust that this was a serum rash; the patient should be isolated instantly.

Dr. C. R. BOX did not agree with Dr. Goodall that the rash of scarlet fever never appeared on the palms and soles, although it was certainly rare in these positions. If attention were paid to glandular enlargement a clue might be obtained to the differentiation between scarlet fever and rubella. Serum rashes might be scarlatiniform, but if the patient were examined thoroughly it would generally be found that the

rash was not uniform and that there was marginal erythema or some sort of discrepancy which would enable one to attribute the rash to the proper source. He did not believe in influenzal rashes; all cases of so-called influenzal rash which he had seen proved to be undoubtedly something else.

Dr. FREDERIC THOMSON said that in the small-pox epidemic of 1901-2 fully 50 per cent. of the mistakes in diagnosis were due to a confusion between small-pox and chicken pox. In the course of that epidemic Dr. Rickotts said to him that he would be prepared to make a diagnosis between the two conditions over the telephone if there was a good observer at the other end to describe the distribution of the rash. The differentiation of scarlet fever from rubella was often difficult, sometimes impossible. The glands were not always enlarged in rubella. The only help that he had found was the colour of the eruption; rubella very seldom lost its pinkish tinge, which was practically never found in scarlet fever.

Sir J. DUNDAS GRANT raised the question of post-operative scarlet fever, and whether the rash seen after operation was due to drugs. Some people had a rash of an erythematous kind after potassium bromide, quite apart from the ordinary bromide rash. Dr. W. STOCKER said that vomiting was one of the greatest diagnostic points in scarlet fever, differentiating it from measles and rubella. The glands in the neck, which were nearly always tender and enlarged in rubella, were a valuable sign in that condition. Dr. J. H. STOWERS said that for a number of years he had observed—not an original observation—that the vesicles of varicella were very frequently ovoid rather than oval, and with their long axes always across the axis of the body. It was important to study drug eruptions, which were extremely common; he believed there were 150 of them.

Dr. GOODALL, owing to the lateness of the hour, was unable to make a detailed reply. He could only say that in his belief surgical scarlet fever was scarlet fever pure and simple. Rashes after operation were not generally scarlatiniform.

REPAIR OF BONE INJURIES.

A MEETING of the Sheffield Medico-Chirurgical Society was held on February 16th at the University, Sheffield, with the President, Dr. GODFREY CARTER, in the chair. Mr. E. W. HEY GROVES read a paper on "The repair of bone injuries," and referred to his experiments with metal plates on fractures in animals, which showed that the presence of metal was not prejudicial to new bone formation. It was to the methods of dealing with gaps in bone and the principles involved in filling them that Mr. Hey Groves mainly directed the remarks of his paper. He pointed out that powdered bone put between a gap was not useful, and that comminuted bone was satisfactory provided there was no interference with its blood supply. The use of a dead graft was almost as good as a living one. The importance of firm fixation of grafts was emphasized and of wide contact between the bone of the host and of the graft as being factors which promote and stimulate osteogenesis. The paper was beautifully illustrated with lantern slides, showing some of the methods used by the lecturer. In the discussion which followed, Professor CONNELL, Mr. GRAHAM SIMPSON, Mr. FINCH, Mr. GARRICK WILSON, Mr. COUPLAND, and others took part.

At the annual dinner of the Odonto-Chirurgical Society, held at Edinburgh, Mr. A. E. MILLAR, in proposing the toast of "The Royal College of Surgeons of Edinburgh," suggested that the creation of a fellowship in dental surgery would be an incentive to those who had time to spend in dental research. Mr. George Mackay, F.R.C.S.E., in reply, said that diplomas were multiplying in all directions, and there was a tendency to too much specialism; it did not do to allow men to get into too narrow grooves. Mr. A. Miles, F.R.C.S.E., in proposing "The Edinburgh Dental Hospital and School," said that the dental profession was in a transitional period. The passing of the Dental Act last year meant that the college and school would have certain additional duties. Whatever its features the Act was on the Statute Book, and it was for the college and school to carry it out to the best of its ability. Edinburgh was fortunate in being well represented on the Dental Board.

THE Society for the Advancement of Clinical Study in New York announces that the principal hospitals of New York are joining in a plan to provide daily medical clinics open to all members of the medical profession. Dates will be arranged so that at each hospital at least one clinic will be held daily, and subjects of importance will be covered at regular intervals.

Reviews.

THE SURGERY OF PERIPHERAL NERVE INJURIES.

In *The Surgery of the Peripheral Nerve Injuries of Warfare*, Mr. HARRY PLATT has given an admirable summary of the subject, and almost the whole of the views expressed would be endorsed by those who have had much experience of the injuries of peripheral nerves resulting from gunshot wounds. His personal experience embraces some 500 operations for such injuries, and the value of his conclusions is greatly enhanced by the fact that the clinical and pathological aspects have been worked out in collaboration with Professor Stopford and others. These conclusions will be found to harmonize in all essential respects with those of other workers in the same field.

Anatomical and physiological considerations receive due emphasis, and the practical methods of clinical examination which have crystallized from the more elaborate and detailed methods of research are well summarized.

Mr. Platt's classification of the gross injuries which may be found as the result of gunshot wounds is perhaps too elaborate, and is of little practical use, since it rests upon an anatomical rather than upon a physiological or functional basis. The same criticism is applicable to the well-known grouping of Benisty, which he quotes.

In regard to the repair of divided nerves, Mr. Platt emphasizes the fact, now generally recognized, that the only method which offers any prospect of restoration of function is direct end-to-end suture; and the various manoeuvres for overcoming the difficulties presented by a wide gap are discussed. His experience of nerve grafts coincides with that of most other surgeons. There is no doubt that a few meagre fibrils can sometimes be found in an excised graft, and it is equally beyond doubt that close examination has sometimes revealed evidence of conduction through a graft; but no unequivocal facts have yet been adduced to prove that useful function can be restored by nerve grafting.

Mr. Platt's analysis of results deserves very careful attention. He has tabulated those of end-to-end suture in 150 cases in as fair a manner as possible, since he specifies the nature and, to some extent, the degree of the recovery. He does not, however, give the criteria by which recovery of the muscles was judged, whether by the standard of function or merely that of electrical tests. It is noteworthy that in 77 cases in which either the median or the ulnar nerve was sutured recovery in the muscles of the hand was observed in only 23 instances.

With regard to sensory recovery Mr. Platt's experience fully justifies the pessimistic view to which other surgeons have been driven—namely, that "in very few cases has there been more than a slight recession of analgesia or incomplete restoration of protopathic sensibility." His general conclusion is that "in the whole series (of 150 end-to-end sutures) there are no examples of absolutely complete and perfect recovery, excepting possibly in five of the musculo-spiral and two of the external popliteal sutures."

It is perhaps a little surprising that so few cases of causalgia are included in the series, and that Mr. Platt should not have encountered a single instance of the severe type of case in which no surgical procedure, not even section of the posterior roots, gives any relief. The only serious criticism which must be made in this connexion concerns the preference expressed for resection and suture as against the "equally or even more destructive method of alcohol injection." Alcohol injection cannot be more destructive than resection, and may be much less so. If properly controlled, pain may be abolished without causing total loss of conduction, and even if such total loss is occasioned recovery is much more rapid and satisfactory, since the anatomical continuity of the nerve has been less disturbed.

The book contains a large amount of information in a small compass; it is well arranged and clearly written, and deserves careful perusal by all who are interested in the subject.

THE WASSERMANN TEST.

As Colonel CRAIG is an acknowledged authority on the technique of the Wassermann reaction the appearance of the second edition of his book² on this subject was to be expected. While it corresponds in plan and matter to the first edition care has been taken to add any new or recently observed facts. It is thus thoroughly up to date.

Veneral diseases and the problems, both social and scientific, which they present are at the moment receiving considerable attention. This work will serve those interested in the subject well, since it expresses in a manner both lucid and thorough the latest information on a large part of the various aspects of syphilis. But it does more than this: it embodies some things not generally known, such as that the strength of the Wassermann reaction undergoes marked daily variations. This observation must have considerable point when a comparison between the technique of different workers is being made, or when a series of observations are being carried out on the same individual. Again, the author advises that if a human blood cell suspension is employed, only blood from Group IV should be used.

While the subject matter will appeal especially to pathologists, there is also much useful clinical information. Colonel Craig's position as a leading authority on the subject adds to the value of his statements, for the reader is assured that only carefully tested facts have been recorded. The book is a most valuable contribution to an important subject.

HYPERPIESIA.

SIR CLIFFORD ALBUTT defined hyperpiesia as a malady in which at or towards middle life the blood pressure rises excessively—a malady having a course of its own, and deserving the name of a disease, but without any organic associations other than cardiac hypertrophy and altered blood vessels, the raised blood pressure or hyperpiesis being a sign of the disease hyperpiesia. It is therefore most appropriate that Dr. BARRY SHAW should dedicate to him this careful clinical, pathological, and experimental study of *Hyperpiesia and Hyperpiesis (Hypertension)*,³ which is obviously the result of years of thoughtful work, and indeed embodies ideas incidentally introduced into some of his previously published papers. The basis of this finely got up volume is the record of fifty cases of hyperpiesis clinically and pathologically investigated at University College Hospital, the clinical diagnosis depending on a systolic blood pressure, taken on the upper arm in the recumbent position, of 150 mm. Hg or more. But three of these cases did not show cardiac hypertrophy at the necropsy, and are therefore excluded from the detailed analysis, the high blood pressure being due to intracranial haemorrhage in two instances, and to excitement in the third. Three-quarters of the patients were males, but as boys and young adults may be affected laborious occupations can be held to be not responsible. The largest number of deaths occurred between 40 and 49 years of age, and the view that hyperpiesis is a function of age is erroneous, for the blood pressure of vigorous old men may be constantly below 150 mm. The most frequent symptoms were cardiac, such as dyspnoea on exertion, dropsy, and palpitation; almost as common were renal manifestations, and it is noteworthy that granular kidney was found after death in about half of the cases; nervous symptoms came next, and then those referable to the gastro-intestinal tract. The clinical analysis is followed by some histological remarks, illustrated by a number of figures, on renal atrophy by Mr. T. W. P. Lawrence, and then the microscopic changes in the 47 cases are considered in two groups: in 26 cases a kidney was injected with a preservative fluid as soon after death as possible, whereas in the remaining 21 cases this was not done; as degenerative changes in the renal tubules were found in 80 per cent. of the second group as compared with a 60 per cent. incidence in the first group, the question arises whether this difference was due to post-mortem autolysis. The causation of the raised blood pressure is discussed at length, and the view that it is due to widespread obliteration of the small blood vessels is controverted; the influence of some pressor substance or substances is

tentatively accepted. On this subject Dr. Batty Shaw has carried out some experimental injections of tissue extracts into animals on the lines adopted by Svale Vincent and Shoen and by Tigerstedt and Bergman; it appears that a pressor substance—rennin—is present in the normal kidney, especially in the cortex, and it is suggested that in cases with definite changes in the kidneys the hyperpiesia may be due to nephraemia or to the entrance of rennin into the circulation. But in cases with unaffected kidneys pressor substances from sources other than the kidneys, such as the intestinal tract, must be considered. It is indeed admitted that all cases of hyperpiesia may be due to toxins of extrarenal origin and that changes in the kidneys may be caused by their influence. The possibility of anaphylaxis in this connexion is cautiously raised, and the resemblance of the hypopictic crises—characterized by a sudden fall of blood pressure, convulsions, and even collapse—to histamine shock is pointed out; formerly ascribed to metabolites retained as the result of renal inadequacy, these attacks may, it is suggested, be due to histamine-like bodies derived from cells deprived of their blood supply, and be analogous to protein shock. This careful clinical and pathological investigation will appeal to others engaged on similar problems.

PHYSIO-THERAPEUTICS.

THE effects of the experiences of the last seven years on the practice of surgery and medicine have been great and manifold. We are reminded by the appearance of the second edition of Dr. T. D. LUKE's *Manual of Physio-Therapeutics*⁴ that that department of treatment has benefited as much, probably, as any other. The great number of men whose physical apparatus has been damaged, and of whom many at the same time have experienced disturbances of their psychical endowments, has offered a great field of work for massage, muscular training, electro-therapeutics, hydro-pathy, and the like.

In all medicine when we attempt to study the effects of treatment we are met by the difficulty of distinguishing between the actual physical results of a remedy or the actual physical changes produced, and the results suggested to the patient by the physician and his assistants, which are often duly experienced by him, without perhaps any physical change having taken place. In no department of medicine and surgery is this difficulty more obvious than in that treated in the work now under notice.

But although this may be annoying to the scientific investigator it is of little moment to the patient, who does not care how he is cured so long as he feels that he is. As the anonymous writer who is quoted on the title-page says, "Most folks like being healed by magic." Without attempting to estimate how much magic and how much physics there may be in physio-therapeutics, we can recommend Dr. Luke's book to all who wish to obtain an insight into the many methods of treatment which are so largely employed at spas and hydro-pathic establishments. The book is not one on war injuries, and thus very little is said about the orthopaedic treatment of war disabilities. The section on thermotherapy is particularly good, and hydrotherapy, massage, and medical gymnastics are adequately discussed. The author is moderate in his claims for massage, and his remarks on the effect of exercise on the heart and on the metabolism of the body are sound. We must confess, however, that we have found it as difficult to estimate the difference between one professor's set of physical jerks and another's as it notoriously was to tell the difference between Tweedledum and Tweedledee. The movements taught by Jones-Brown seem to us of about equal merit to those of Smith-Robinson, or any professor with a Tontonic surname.

Dr. Luke includes a wide range of methods of treatment in physio-therapeutics, including sea voyages, the open-air treatment of consumption, climate, electro-therapeutics, and diet, to which last subject a whole section is devoted.

We venture to doubt the accuracy of his statement that the Chinese and Japanese are strict vegetarians. We believe it is a fact that flesh and fish enter into the diet of these peoples whenever they are able to obtain them. The chapters on the dietetic treatment of obesity, diabetes, and rheumatism are likely to be useful to the practitioner.

We have failed to find any reference to the sun-rays treatment of surgical tuberculosis by the brothers Rollier, which

² *The Wassermann Test*. By C. F. CRAIG, M.D., M.A., F.A.C.S. Second edition, revised and enlarged. London: H. Kimpton. 1921. (Med. 8vo, pp. 273; 3 plates. 25s. net.)

Oxford Medical Publications. London: Henry Frowde, and Hodder and Stoughton. 1922. (Cr. 4to, pp. 191; 11 figures, one coloured, 55 charts. 21s.)

⁴ *Manual of Physio-Therapeutics*. By THOMAS DAVEY LUKE, M.D., F.R.C.S.E., etc. London: William Heinemann, Ltd. New and revised edition. 1922. (Demy 8vo, pp. xvi + 499; 210 figures. 25s. net.)

is carried on at Leysin, or any mention of the melted hard paraffin baths which have proved useful in the military orthopaedic hospitals.

The book is printed in clear type on good paper, is well illustrated, and has an adequate index.

COLLOIDS.

HATSCHEK'S *Introduction to the Physics and Chemistry of Colloids*⁵ is a textbook dealing with the scientific knowledge of the subject acquired down to the present time. Many of the facts depending on colloidal properties are among the most familiar of everyday life, yet of the subjects of common experience few received so little scientific attention as these for long after the foundation for their study had been laid by Thomas Graham more than fifty years ago.

The reason for past delay in the pursuit of investigation in the phenomena of colloids was apparently that the suggestion which leads to experiment was then lacking through the want of subsidiary information relating to the causes concerned. With the growth of science in other branches of molecular physics came the needful suggestions, and more recently direct appeals to experiment have been frequent and fruitful of results. The information derived from experimental work has, however, been rather inaccessible to the reader who could not devote time to the study of original memoirs or work out for himself the inferences deducible from different workers' achievements.

That defect is now repaired in the admirable little volume under review. It treats the subject in the easy manner that captivates interest; it describes the qualities of colloidal matters and their behaviour under experiment with quite vivid effect, enabling the reader easily to visualize the experiment even if a stranger to the materials concerned; the explanations of theory are equally lucid. The brevity of expression with which this is accomplished adds to the meed of praise which is the author's due. A great and varied range of facts are treated, and nothing of especial or even ordinary interest appears to have been omitted; the discussions of fact and theory are rendered in such order as best to facilitate a grasp of the whole subject and to give connected ideas of related phenomena. Throughout the text proper recognition is paid to those who have done the scientific work, and references to original publications are sufficiently numerous to meet the needs even of the specialist reader.

No one who is interested in the study of colloids owing to their importance in biology and industry or other relations should neglect to become acquainted with the contents of this book. It should be no less appreciated by elderly students than by their juniors, and among the latter there should be many to whom it will prove a strong incentive to research.

AGRICULTURAL AND INDUSTRIAL BACTERIOLOGY.

The activities of bacteria are being studied by agriculturists, dairy farmers, and manufacturing chemists with as much enthusiasm as has been shown by medical bacteriologists since the days of Pasteur. Professor R. E. BUCHANAN'S book on *Agricultural and Industrial Bacteriology*⁶ discusses the science of bacteriology from the industrial point of view. The medical bacteriologist frequently encounters organisms used in industrial processes, and from the public health point of view the medical man should have some acquaintance with the bacteriological questions involved in dairy work, and in the baking, bottling, and canning of food.

Professor Buchanan's book is not a manual of laboratory practice so much as an exposition of the bacteriological topics of fundamental importance in everyday life on the farm and in the industries. The first section is devoted to a classification of bacteria, yeasts, and moulds. The second section deals with methods of study, and contains a useful chapter giving tests for the determination of microbial activity. The physiology of bacterial processes forms the subject matter of the third section, and in it the chemistry and physics of these reactions are discussed in the light of present-day knowledge. The fourth section deals with such practical questions as the

preservation of food, alcoholic fermentation, bread making, the manufacture of cheese, vinegar, and citric acid, and the fermentation of starch. Considerable space is devoted to soil bacteriology and the nitrogen cycle, a subject of vast importance to agriculturists. When the author comes to the question of micro-organisms and disease he is not quite so much in his element: the short description he gives of pathogenic organisms is insufficient for the recognition of species, and the illustrations of bacteria surrounded by flagellae might lead the novice to imagine that such morphological appearances are of value in identification. The last section of the book gives a clear exposition of the bacteriology of water, sewage, and milk.

The nomenclature adopted is slightly different from that followed in most English books. For instance, the author describes the Gram-negative cocci under the name of *Neisseria*, the fluorescent bacilli under the name of *Pseudomonas*, and all the anaerobes under the title *Clostridium*. Apart from the nomenclature the classification adopted is very involved, and it would take almost as long to place an organism in the particular group to which the author wishes it to be assigned as it would to identify it. In the opinion of most bacteriologists it is unwise to attempt too strict a classification in the present state of our knowledge of bacterial species. What is chiefly required is accurate description and ease of identification. There can be no question, however, that the information with which this book is so closely packed will be received with gratitude by those who, either for practical or theoretical reasons, are interested in the manifold activities of our bacterial enemies and friends.

NOTES ON BOOKS.

STARTING from the thesis that tuberculin contains a curative principle, the action of which is masked and generally rendered impotent by undesirable protein impurities evolved in its production, Professor GABRILOVITCH of Finland, in a monograph written in French,⁷ sets out to convince the reader that he has discovered a tuberculin of considerable efficacy in the treatment of tuberculosis. This tuberculin is referred to as T.P.G.—"tuberculine pure Gabrielovitch"—and has been deprived of the protein impurities which, according to the author, produce the general and the toxic phenomena. How this purification is obtained is apparently a secret which he prefers to keep to himself. It is true that he mentions the fact that he has solved the difficult problem by laborious investigations (the phrase is familiar) and by the use of "appropriate" reagents, such as "xylo, ether, chloroform, caustic soda, hydrogen peroxide, etc.," but such a statement conveys little information. For a hundred pages he tells us over and over again the various beneficial effects that follow the use of T.P.G., citing names of professors and doctors in various countries (alas! there is not a solitary one from this sea-girt isle) who have found in T.P.G. a boon and a blessing to man. But we are afraid that those who look for a sign will not be convinced.

The second edition of Dr. LYLE'S *Manual of Physiology*⁸ has been brought up to date and extended. The author has had the co-operation of Dr. DE SOUZA throughout. The book is quite a good example of a short manual of the subject, concise and well arranged. The authors have succeeded in giving a good general review, without unduly stressing any particular phase. The facts presented have, on the whole, been well selected, and, considering the size of the volume, there are but few omissions of any great importance. In view of the number of references in current medical literature to hydrogen ion concentration a somewhat fuller explanation might have been included with advantage. The authors throughout have managed to present the physiological data with their medical or clinical bearings. It is too often forgotten that the majority of students attending classes in physiology are going to be, not specialists, but practitioners of medicine. The book contains 3 plates and 139 figures in the text.

MEDICAL AND SURGICAL APPLIANCES.

A Combined Anaesthetic Apparatus.

DR. FRANCIS E. SHIPWAY (London, W.) sends an account of a combination based upon the apparatus for administering warm anaesthetic vapours. It consists of five principal parts mounted on a wooden base—namely, an ether bottle (E), a Dudley Buxton's chloroform bottle (C), a mercury safety valve (S), a sight-feed, mixing chamber (M), and a thermostat flask of quart capacity for warming the issuing vapour. The ether and chloroform bottles stand in metal jackets partly filled with warm water in order to prevent excessive cooling of the anaesthetic. A regulating tap (T) directs the flow of air or gas, either straight to the patient, or through the anaesthetic in any desired proportion; it passes then to a double metal tube (b) immersed in the hot water of the thermostat flask. A tap (F) is provided for replenishing the ether supply during intratracheal insufflation (Dr. Shipway expresses his indebtedness to Dr. Stanley Rowbotham for permission to use this excellent device). When the apparatus is to be used for the insufflation of ether or nitrous oxide-oxygen-ether, or the inhalation of nitrous oxide-oxygen-ether, the chloroform bottle should be detached, and the efferent limb of (T) joined direct to (D). For intratracheal insufflation of ether, a foot-bellows or motor pump is connected to the efferent limb of (T). By opening the tap (F), the pressure is reduced when desired. For the inhalation or insufflation of nitrous oxide-oxygen-ether the tubes of the mixing chamber, which are marked N_2O and O_2 , are attached to the nozzles of their respective cylinders, which are three in number—namely, two N_2O cylinders of 50 or 100 gallons capacity, and one O_2 cylinder of corresponding size; they are placed vertically in a three-ringed holder screwed to an upright rod; the lower end of this upright is fixed to a wooden base, and the upper end carries a metal plate, which supports the combined apparatus at a convenient height from the ground. A spirit lamp is used to keep the nitrous oxide valve warm; this ensures a steady flow of the gas. In all cases the vapour is administered warm. A further advantage is that induction can be carried out with nitrous oxide-oxygen-ether, the intratracheal catheter passed, and anaesthesia continued if desired by the insufflation of these gases. The apparatus has been made by Messrs. Mayer and Phelps, New Cavendish Street, W.

BISMUTH IN THE TREATMENT OF SYPHILIS.

NUMEROUS attempts have been made, and no doubt others will be made in the future, to obtain chemical substances which are improvements on, or substitutes for, the arsenical compounds introduced by Ehrlich in the treatment of syphilis. Apart from the efficacy of the drug, which is of course the first consideration, simplicity of preparation, stability of the substance, facility of administration, and absence of toxic effects are the chief desiderata. Recently attention has been directed to the promise offered by the use of salts of bismuth.

Sazerac and Levaditi¹ reconvert their essays with various bismuth preparations employed in the treatment of experimentally produced spirochaetal lesions of rabbits. The animals were infected with two races of *Spirochaeta pallida*, one derived from a syphilitic chancre and the other obtained from the blood of a general paralytic, and with a spirochete of a different order—*Spirochaeta eumeli*, which is the organism found in the spontaneous spirochaetosis of rabbits. Of the various bismuth salts tried (bismuth citrate, lactate, subgallate, oxydodogallate, and other linkages) the one found to be best supported and to give the speediest results was the tartrobismuthate of potassium or sodium. This salt, containing approximately 50 per cent. of bismuth, was prepared according to the method given by Cowly,² and it was found to be well supported by the rabbit to the extent of 50 to 60 mg. per kilo of body weight when administered subcutaneously or intramuscularly. Intravenously the salt was much more toxic, as less than a tenth of that dose was fatal to the animal. A suspension of the drug in olive oil, sterilizable in the autoclave without decomposition, was found to be less toxic than an aqueous solution. When this was injected subcutaneously or intramuscularly into infected animals the spirochaetes disappeared from the lesion on the second or third day, and rapid cicatrization followed. Administration by the mouth or rectum gave poor results. Applying the results to the therapy of human syphilis the authors soon discarded the use of aqueous solutions, as they caused pain and local reactions. The same salt, however, in oily suspension was much better tolerated when given intramuscularly, and though the action may perhaps have been slower they believe it to be more constant, more profound, and more lasting. As the result of the treatment of a few cases in various stages of syphilis, Sazerac and Levaditi state that there is a rapid disappearance of spirochaetes from the open lesions, and a cicatrization of these lesions in a few days. The tartrobismuthate acts on the primary and secondary adenopathies and favourably

influences the tertiary lesions. In none of the cases treated was there any sign of relapse after some severe months of observation. The treatment had the minor drawbacks of producing a slight dark line on the gums comparable to the blue line in plumbism, and of inducing sometimes a stomatitis which easily yielded to local treatment.

The time has been too short and the cases too few to permit of a definite conclusion being drawn regarding the permanence of the cure, but the authors believe that in bismuth we have a spirillicide of remarkable potency, comparable to that of the best antisiphilitic medicaments known. It seems to act better and more profoundly than mercury, though in some cases less rapidly than the most active arsenical derivatives. The stability *in vitro* of the bismuth salts used is certainly a notable advantage from the point of view of therapeutic practice. Sazerac and Levaditi are now engaged in the preparation and testing of more complicated bismuth derivatives.

Meanwhile Fournier and Gnénot have made a more extensive study of the effects of the bismuth treatment in human syphilis, clinically and serologically, endeavouring to define the dose and to appraise the possible disadvantages as well as the benefits of the drug. Having treated about 200 cases, they state that the results the treatment has given in their hands absolutely confirm those of Sazerac and Levaditi, and show that bismuth deserves to be considered as one of the most powerful antisiphilitic agents at our disposal. The effect of the tartrobismuthate on the primary lesion is to cause a disappearance of the spirochaetes from the surface of the chancre, sometimes on the day after the first injection, more usually on the second day, and rarely after the third day. Small erosive chancres cicatrize completely in a few days, medium-sized chancres take a week to a fortnight, and very large or ulcerating chancres heal entirely in about three weeks, though they lose their specific characters at an early period. The chancrous induration and the accompanying adenopathy are more rapidly influenced by the bismuth than by any other treatment whatever, and generally have completely disappeared in a few weeks. Spirochaetes have been sought in vain in the glands after the third injection—that is, about a week from the commencement of treatment. The clinicians report that in all the primary cases they treated the results were uniformly good, from both the clinical and serological points of view.

In cases where treatment was not begun until the secondary manifestations were evident no less striking results were obtained. The spirochaetes disappeared from mucous plaques after the first or the second injection, and these lesions might heal completely in four or five days. The erosive genital plaques healed almost as rapidly. If caught at its commencement the roseola was arrested, perhaps after an exacerbation of twenty-four hours. The Herxheimer reaction might be apparent also at the site of the papular syphilides. The simple roseola was generally effaced entirely in five to ten days, though the papules endured a little longer. Indeed, the authors have seen the total disappearance in fifteen days of a generalized miliary eruption and of palmar syphilides—manifestations which are notoriously rebellious to specific treatment. The general secondary phenomena, such as headache, lumbago, and pains in the bones, always disappeared with the first injections. In particular they draw attention to eight cases which, in spite of prolonged arsenical and mercurial treatment, were subject to recurrent lesions, and which were permanently cured by bismuth; and to another case of acute syphilitic meningitis where all the symptoms—headache, rigidity of the neck, and Kernig's sign—disappeared after three or four injections, whilst the lymphocyte count of the cerebro-spinal fluid fell from 400 to 7 on the fifteenth day.

With regard to tertiary lesions, Fournier and Gnénot report that most usually the bismuth treatment acted in a remarkably rapid fashion in those forms commonly met with, such as gumma, osteo-periostitis, and ulcerated cutaneous sores; lingual leucoplakia was improved though not cured; and the time has been too short to enable a judgement to be formed on the results of treatment of cases of visceral and nervous syphilis.

In brief, as far as the authors have gone, they have not yet encountered any case which presented new lesions after the commencement of treatment; no chancre treated before the appearance of roseola, even if it had been in existence for over a month, was followed by secondary lesions.

The Wassermann reaction has been the guide for the duration of the treatment; in primary and secondary cases

one course of treatment is not usually sufficient to bring about a negative serological reaction. The tartrobismuthate (10 per cent. in olive oil) is administered intramuscularly twice or three times a week, beginning with a quantity corresponding to a dose of 20 cg., which is repeated once or twice and then followed by a dose of 30 cg., so that a first course of treatment taking a month means the injection of a total of 2 to 3 grams of the salt. After this has been completed a single weekly injection of 20 to 30 cg. may be given, or the treatment may be suspended for a month and then started over again. All the time the condition of the Wassermann reaction is noted, and when this becomes negative a few more injections may be given as a precautionary measure.

No serious phenomena have resulted from the use of bismuth, but there are two inconveniences on which Fournier and Guénot dwell. The first of these is the local reaction. Though well borne by most patients, yet in some instances the injections provoked sharp pains at the site, which might last for two or three days, sometimes accompanied by local redness and swelling and in exceptional cases by local oily collections, which were spontaneously and rapidly absorbed. These occurrences were practically confined to patients who had walked shortly after being given an injection. The other drawback noted was the almost constant impregnation of the buccal mucous membrane with bismuth. This was manifest by the appearance of a dark line on the gums, sometimes by black patches on the inside of the cheeks and a slight bluish tint of the tongue; in certain cases a mild stomatitis appeared, easily prevented and easily curable. Chemical examinations showed the presence of bismuth in the blood, cerebro-spinal fluid, bile, sweat, saliva, faeces, and urine. It is found in the urine in eighteen to twenty-four hours after the first injection, and persists for twenty to thirty days after treatment is suspended. If the urine is examined in a vessel a black deposit of bismuth will be found on the sides, due to the fermentation of the urine.

In the same number of the *Annales Marie and Foucade* report a trial of tartrobismuthate on twenty cases of nervous syphilis. Not much can be expected from the treatment of such conditions, but sensible improvement resulted in a few cases where the lesion was localized and not diffuse.

The experimental and clinical records of this bismuth treatment show a welcome degree of restraint that should serve as a model to those who may follow up the observations.

A CONTRIBUTORY SCHEME FOR THE HOSPITALS OF LONDON.

On February 27th the Secretary of King Edward's Hospital Fund for London addressed a circular letter to the chairmen of the various metropolitan hospitals reminding them of the two money-raising schemes submitted at the close of last year to the London Regional Committee of the British Hospitals Association.

The Regional Committee, after consulting the constituent hospitals, submitted to the King's Fund on January 12th two schemes unanimously approved in principle by that committee, with a proviso in the case of the contributory scheme that before contributions were collected under it counsel's opinion should be obtained that it contained no contract for treatment, express or implied. The scheme was then redrafted, after consultation with Mr. Douglas Hogg, K.C., with a view to meeting apprehensions expressed by the medical members of the Council of the King's Fund. The revised scheme, together with counsel's opinion, is as follows:

KING EDWARD'S HOSPITAL FUND FOR LONDON.

London Hospitals Contributory Scheme.

Objects of the Scheme.—To enable wage-earners by means of an organized system of moderate and continuous contributions (i) to give voluntary assistance to the hospitals of London in carrying on their work of curing disease and alleviating suffering, and (ii) to be relieved, together with their dependants, from all hospital charges when receiving hospital services.

Need for the Scheme.—The expenditure of the hospitals has grown enormously in recent years, partly owing to the rise in wages and in the price of provisions, fuel, etc., and partly owing to the costliness of the equipment needed to fight disease by modern methods. The result is that very many of the hospitals are overwhelmed with debt, and in some cases they have had to close

many beds. While they will continue, in accordance with the principles on which they were founded, to care for the necessitous poor without payment, they can no longer exempt from payment persons in receipt of good regular wages or income. Many hospitals are already making charges towards the cost of maintenance, but such charges represent only a fraction of the cost, and even so are frequently too heavy for patients to pay when incapacitated by illness. It is only reasonable, therefore, that the classes from which the majority of hospital patients are drawn should save while in health for the hospitals, and that the savings should be pooled, so that when a contributor has been admitted to hospital treatment a fund may be available to lighten the burden of the hospital.

Scope of the Scheme.—It is not intended that hospitals should afford any facilities other than those already provided by them, or that any alteration should be made in the arrangements now in force at individual hospitals for the admission of persons as in-patients or out-patients, or for their treatment by the medical staffs: the hospital will continue to decide what cases are suitable for hospital treatment, and the order of priority in which applicants are to be admitted. The scheme has nothing to do with National Health Insurance, and leaves untouched the position and responsibility of the general practitioner; it does not cover ordinary maternity cases or any treatment for which provision is made by the State or local authorities.

Who may Join the Scheme.—In order to avoid abuse by those who can afford to pay for treatment outside the hospital, it is necessary to fix a strict income limit. Accordingly, the scheme is confined to persons whose individual income does not exceed £4 a week for a single man or woman, £5 a week for a man and wife with no children under 16, £6 a week for a man and wife with children under 16. Such persons being employees in a factory or other unit of employment, or members of societies established for mutual benefit, will join in groups.

Organization.—All contributions will be collected within the factory or other group and will be paid over to a central organization distinct from the King's Fund and from any individual hospital, but so composed as to secure the co-operation of all interests concerned. This organization will, unless and until hospitals otherwise arrange, distribute the funds collected under the scheme, after deduction of expenses of collection and administration, as payments towards the cost of patients after admission to hospital.

Conditions.—Regular contributors of 12s. per annum paid in one sum in advance, or 13s. per annum paid in weekly instalments of 3d., will, together with their wives and children under 16, when accepted for treatment by a hospital, be relieved, by payments made on their behalf by the central organization, from contributing to their cost of maintenance as in-patients and from any charge in all out-patient departments.

7, Walbrook, E.C.4, February 25th, 1922.

Opinion of Counsel.

I have carefully considered the above scheme. In my opinion it is quite clear that the scheme creates no contract of any kind with a contributor to give him treatment.

(Signed) DOUGLAS MCGAREL HOGG.

Temple, February 24th, 1922.

At a special Council meeting of the King's Fund held at the House of Lords on March 8th, with the Earl of Donoughmore in the chair, Lord Somerleyton presented a report of the Management Committee, and moved the adoption of recommendations on the subject of the proposed contributory scheme and the combined public appeal. The motion was seconded by Sir Cooper Perry. Amendments proposed by Sir William Collins and the Speaker of the House of Commons having been accepted, the resolutions were passed in the following form:

- (i) That the scheme as redrafted be accepted in its main lines by the General Council as removing the reason for postponing the contributory scheme.
- (ii) That the King's Fund should not itself administer a contributory scheme, but should, through its propaganda for the combined public appeal, assist all hospitals in their efforts to secure support from the classes whose members are treated in hospital; and should assist such hospitals as, after consultation with their medical staff, desire to initiate mass contributions in various forms.

An anonymous gift of 100,000 dollars has been made to Yale University for the establishment of a professorship in honour of Dr. William H. Carnall, who retired a few years ago after fifty years of distinguished service in surgery.

At the recent annual meeting of the New York Tuberculosis Association Mr. G. J. Drolet, statistician of the Association, stated that in New York City the coming into the population of a large Jewish stock, noted for their immunity to the diseases of congested city life, had been a considerable factor in reducing the death rate from tuberculosis. The lowest mortality prevailed in the districts which were largely Jewish, whereas in the districts where the poorer immigrants of Irish and Italian stock lived, as well as in the artist and Bohemian colonies of Greenwich Village, the tuberculosis death rate was very much larger.

INSANITY AND THE REPRODUCTIVE GLANDS.

PSYCHIATRISTS have long recognized the intimate relation between disordered sexual function and insanity. It is in adolescence, when new and disturbing forces surge into activity, that this relation is observed most clearly. At this time the process of development is subjected to a severe strain, and the individual has to adjust himself to unaccustomed feelings and needs; it is then that any tendency to instability is apt to find manifest expression in forms which vary from the milder neuroses to the graver psychoses. The Morison Lectures and the Maudsley Lecture for 1921, both delivered by Sir Frederick Mott, constitute a notable addition to our knowledge of this aspect of psychiatry.¹ The Morison Lectures are concerned with the psychopathology of puberty and adolescence, and Sir Frederick Mott points out that the lecturer of 1890, Sir Thomas Clouston, made it one of the objects of his lectures to show the relation between the physiology and pathology of reproduction to the neuroses and psychoses. At this time our knowledge of the reproductive endocrine system was only in its infancy, but the recent researches on the pathological changes found in cases of dementia praecox have served to demonstrate the organic conditions which find expression in this grave form of mental disorder. Feeling convinced that certain forms of mental disease were correlated with morbid changes in the reproductive organs, Sir Frederick Mott has made histological examinations of these organs obtained from patients of both sexes dying in asylums. The research is all the more valuable as it was controlled by an exhaustive study of the human testis and ovary, at various ages from birth onwards, of individuals dying from various injuries or disease. A full account of this investigation was published in the *BRITISH MEDICAL JOURNAL*, November 22nd, 29th, and December 6th, 1919, and on the last date comments were made on the research in a leading article. It thus suffices to state briefly that demonstrable changes were discovered, which definitely indicated the existence of regressive atrophy in the testes and ovaries in cases of dementia praecox. In the male, spermatogenesis had largely ceased, and in the female the ova had failed to mature. Parallel with this regressive atrophy in the reproductive glands certain changes occur in the central nervous system. These consist essentially of decay and degeneration of the neurones, the nucleus and cytoplasm of the nerve cell being involved without any notable change in the vessels or supporting tissues. The consideration of these facts, together with those known in regard to the biochemistry of the grey matter, leads Sir Frederick Mott to formulate the hypothesis "that the failure of function in dementia praecox may be correlated with a failure of oxidation processes in the grey matter, owing to a deficiency of the vital energy of the nucleus, as shown by morphological and biochemical changes in the nucleus and a failure in the production of the substance which is the antecedent of the Nissl granules."

In estimating the significance of these pathological changes in the reproductive organs and the brain respectively, the view is taken that they are manifestations of one and the same morbid process. It is suggested that dementia praecox is the expression of a failure of vital energy of the cells of the whole body, manifesting itself more especially in the sexual organs and brain, particularly in that part of the brain which constitutes the highest or psycho-physiological level. The biochemical changes in the reproductive organs and the nervous system are primarily of nuclear origin and dependent upon an inborn germinal defect. These researches throw much light on the course and symptoms of dementia praecox, and the views formulated by Sir Frederick Mott are largely in harmony with the clinical facts. It is true that a certain number of cases diagnosed as dementia praecox tend to recover, but the clinical investigations of Kraepelin, in which cases have been followed up for a number of years, make it clear that a more or less unfavourable outcome is probable, and in many instances severe and definite deterioration occurs. And not only the course of the disorder, but the symptoms as well are readily understandable as a premature failure of that vital energy of the organism which derives its main source in adolescence from the activity of the reproductive organs.

If it be the case, then, that the dementia praecox group—in a clinical sense somewhat vaguely delimited—is explicable on the basis of an inherent lack of durability of vital organic functions, the question arises as to how far mental breakdown is inevitable in the subjects of this inborn germinal deficiency. It must be admitted that a large number of these cases have the appearance of complete inevitability; the onset of the disorder cannot be correlated with any external or removable stress, and its course is uninfluenced by any known form of therapy. This, however, is not invariably the case, and a precipitating factor may often be found in some situation which makes unusual demands on the predisposed individual. Dr. J. S. Bolton emphasizes this fact in his work on *The Brain in Health and Disease*. He shows that many cases are especially prone to break down under the mental stress involved in the general change in the function of the cerebrum from the mere acquisition of information to the performance of the higher processes of mind, which change occurs about the period of puberty. This is clearly seen from the fact that overstudy and intense application at this epoch often leads to overstrain of unstable cortical neurones which finds expression in a temporary or permanent attack of insanity. It is also no doubt true, as Bolton further points out, that many mild cases of dementia praecox (premature dementia) are to be found in the outside world. He includes amongst these those individuals who overstrain their mental capacities in youth—both the brilliant student and the one of inferior capacity who obtains a degree by dint of exceptional perseverance—and who in after-life fail to maintain their early promise and lead an ordinary and stereotyped existence. It is probably necessary, therefore, to take a very wide view as to what is included under the heading of dementia praecox, and to recognize that a diminished durability and vitality of biological functions exist, in varying degrees, in a greater number of individuals than is generally supposed.

Observations such as these are not without significance for the clinical psychiatrist; they would seem to indicate, that though dementia praecox has an organic basis, the development of actual insanity in predisposed individuals is not entirely inevitable. If it were more generally recognized that (as is actually the case) many subjects of dementia praecox have since childhood exhibited abnormal personality traits of a type well known to psychiatrists, special measures might be taken to prevent

¹ *Journal of Mental Science*, vol. lxxi, No. 273.

an actual mental breakdown. As it is, the superficial brilliance which these children are apt to display is exploited by their parents and teachers, and they are submitted to the evil effects of intellectual overstrain. It is probably true, also, that many patients in whom the diagnosis of dementia praecox is quite properly made not only make good social recoveries but remain well for a number of years if they lead a life suitable to their physiological disabilities. Unfortunately it often happens that the subject of an attack of adolescent insanity, who makes a good recovery associated with no more than a slight and almost indefinable degree of permanent deterioration, is found to break down again as a result of marriage or pregnancy. In view of the changes which are now known to occur in the reproductive organs in these cases it is readily understandable why such a relapse should take place, and no doubt a number of individuals who eventually become inmates of asylums might remain socially productive for many years if they submitted themselves to a life suitable to their diminished biological capacities. These and other clinical matters are considered throughout the lectures with which our comments are concerned, and more particularly so in a section devoted to the correlation of the morphological, micro-chemical, and chemical changes discovered in the brain and reproductive organs in cases of dementia praecox with the fundamental symptoms of this disorder. It is to be hoped that Sir Frederick Mott will continue these researches at the Maudsley Hospital, since they do much to illuminate one of the most obscure problems in medicine. The conclusions reached in these lectures are the outcome of an enormous amount of skilled and patient research, and the results of further investigation cannot fail to be of great value and interest.

QUACKERY IN RELATION TO DISEASES OF THE EYE.

In his presidential address at the opening of the forty-eighth session of the Bristol Medico-Chirurgical Society, Mr. Cyril Walker gave a racy account of the activity of the quack in the treatment of eye diseases. Scarcely any branch of medicine has been more invaded by advertising charlatans. The term "quack" or "quack-salver" came into common use in the reign of Charles I; it is supposed to have been derived from the noisy, reiterated chatter of the medicine vendor at fairs. The word and its synonyms are common in seventeenth-century works. A quack is defined in the *New English Dictionary* as "an ignorant pretender to medical or surgical skill . . . an empiric or impostor in medicine," but probably Dr. George Gould of Philadelphia puts it better thus: "A quack is a man more interested in himself than in his healing art; caring more for his patent than his patient."

During the Middle Ages treatment of disease of the eye was very largely in the hands of itinerant quacks, who went from fair to fair selling nostrums to the credulous, and couching cataracts when occasion offered. In the time of James I these were first called "oculists," and the term has in consequence never found much favour with members of the medical profession, though the public still cling to it. Certain cures for all sorts of diseases were advertised broadcast in the eighteenth century, and Oliver Goldsmith in his *Citizen of the World* observes, "There must be something strangely obstinate in an English patient who refuses so much health upon such easy terms." Queen Anne, whose weak eyes were a source of much profit to the quack oculists, indulged in quackery on her own account by reviving the very old superstition of "touching" for the King's evil. As there was no scientific ophthalmology

in her day she was the natural prey of quacks. She appointed as her oculists two charlatans: one, William Read, received a knighthood; the other is mentioned by Addison as notorious for "putting out eyes with great success." Read's praises were sung in a hack poem entitled *The Oculist*. With these worthies began the now much coveted and respected title of "Surgeon-Oculist to the King." By far the greatest quack of those times was "the Chevalier" Taylor. He had some claim to be looked on as a qualified surgeon, and was certainly a man of immense energy and ability; but Samuel Johnson, who was well acquainted with John Taylor, described him as the most ignorant man he ever knew. He was appointed "Ophthalmiotor Pontifical" to the Pope and oculist to the Kings of England, Denmark, Poland, Norway, and Sweden. His entry into towns was a sensational affair. In what he calls "the crisis of his grandeur" he travelled "with no less than two coaches and six, above ten servants in livery, besides gentlemen, my companions in my own pay." Gibbon was among his patients, and he operated on Handel for cataract, "but on drawing the curtain we found the bottom defective."

Beside Taylor the quacks of to-day may seem unenterprising; for anything like his audacity one has to go to America. But, as has often been remarked, the love of mystery is deeply implanted in the human breast, and this gives quackery a great advantage over science. Even in France, where the pharmacist is discouraged from selling secret remedies, quack treatments abound. Some are vastly amusing, such as the "cure" investigated by Dr. Darier. It was based on Bier's suction apparatus. Darier submitted himself to treatment with a machine of much splendour, and had demonstrated to him that his vision had been doubled in acuity by suction on his temples. But the patient observed that the test eard had two faces, and the marks exposed on the one side were double the size of those on the other. A German developed a system of ocular signs of disease: the markings of the irides corresponded with certain organs and their diseases. As Mr. Cyril Walker states, "palmistry is credibility itself in comparison," yet the rogue lives to-day; we heard of it as a novelty last year from a most intelligent man, and several inquiries came to us from ingenuous persons who had read of "ocular diagnosis" in the newspapers. At a certain well-known clinic in Germany many sufferers from hopeless conditions used to congregate before the war: all seemed to have had one treatment—the wet pack and mercurial inunction; sufferers from pituitary tumour and from alcoholic amblyopia each got the same.

In England a good deal of humbug is associated with the prescription of spectacles by opticians. Some sight-testing opticians who visit country towns are distinctly amusing. One warns "the incredulous public against unscrupulous imitators," another states that "unless there is a reasonable hope of the patient being benefited he is told so, but should the case present any diminution of hope it is undertaken, and in almost every instance successfully so." The temptation to the optician to order spectacles whether they are needed or not is strong, for he lives by his sales. Mr. Cyril Walker concludes that the best check to quackery is the provision of a sufficient number of capable practitioners able and willing to undertake ophthalmic work. When the doctors do not do this work it is inevitable that the people will drift to the advertisers. He points to the provision made by the State for the treatment of the children in elementary schools, and considers that the parent may reasonably claim the same advantages as his children enjoy. Lastly, the general practitioner should be able at least to decide when to persuade his patients to seek advice, rather than allow them to drift to the sight-testing optician or the quack.

THE CENTENARY VOLUME OF THE ACADEMIE DE MEDECINE OF PARIS.

To celebrate its centenary on December 20th, 1920, the Académie de Médecine de Paris extended its hospitality to thirty-one countries, from which ninety-one delegates were entertained and presented with a beautiful centenary medal designed by Dr. M. P. Richor. The Académie de Médecine has now brought out a sumptuously illustrated and printed volume¹ in commemoration of the centenary. After reciting the original charter granted at the Château des Tuileries on December 20th, 1820, by Louis XVIII, the volume records the proceedings and addresses of the celebration, commencing with the address of M. Laveran, the President, who pointed out that the Académie de Médecine was founded to continue the work of two societies—of medicine and of surgery—which had been dissolved by the convention in 1793, probably because they were suspected of tendencies hostile to those in power. In addition there was a short-lived Académie de Médecine, started in 1804, in the presidential chair of which the well-known Dr. J. I. Guillotin once sat. The first president of honour of the present academy was Baron Antoine Portal, of whose bust there is a fine reproduction. Among the congratulatory addresses presented by the delegates those of the Royal College of Physicians of Edinburgh, the University of Padua, and the Carolin Institute of Medicine and Surgery of Stockholm are artistically reproduced. The other formal addresses by the Secretary-General, Professor O. Aclard, M. Honnorat, Drs. Richelot, D'Espine of Geneva, Vaillard, A. Chanfard, E. Delorme, M. Hanriot, Meillère, and Camus follow; in connexion with Dr. Camus's account of the Academy's activities in vaccination there is a full-page plate containing four portraits: of Lo Duc de Larochefoucauld Liancourt, Fondateur de la Société Centrale de Vaccine; H. M. Husson, Secrétaire du Comité Central de Vaccine; E. Jenner; and William Woodville, who imported vaccine into France in 1800. The record is made especially interesting by the inclusion of fourteen well-executed photographs of the members of the Academy in 1920, arranged in groups representing the various sections.

SURGICAL DISCUSSIONS AT THE GLASGOW MEETING.

THE scientific sections at the ninetieth Annual Meeting of the British Medical Association, to be held in Glasgow next summer, under the presidency of Sir William Macewen, will meet in the University buildings on Wednesday, Thursday, and Friday, July 26th, 27th, and 28th. The names of the officers of sections were printed in the SUPPLEMENT of February 18th, and the provisional programme of the meeting in that of March 4th. The officers of the Surgical Section, of which Professor Alexis Thomson is president, have chosen the following subjects for discussion:—First day: The diagnosis and treatment of cholelithiasis. Second day: The treatment of tuberculous glands. Third day: The surgical treatment of non-malignant affections of the colon. We are asked to say that the secretaries of this section will be glad to receive the names of those desirous of taking part in the discussion of the above subjects, and also the titles of their papers from those desirous of reading papers. The honorary secretaries of the Section of Surgery are Dr. J. A. C. Macewen, 3, Woodside Crescent, Charing Cross, Glasgow; Dr. John Patrick, 9, Newton Place, Glasgow; and Mr. H. S. Sonttar, 59, Queen Anne Street, London, W.1. The local honorary secretary of the Annual Meeting is Dr. George A. Allan, The University, Glasgow.

ROMAN SURGERY IN THE FIRST CENTURY.

As Sir Clifford Allbutt points out in his masterly review of *Greek Medicine in Rome*, it was from the intellectual and agile Greeks that Rome obtained the ideas directing medicine, science, and philosophy; and in the course of this book,

¹ *Centenaire de l'Académie de Médecine, 1820-1920. Publié par les soins du Bureau de l'Académie. Paris: Masson et Cie. 1921. (12 x 8; pp. 278; 21 illustrations. No price.)*

which was founded on the FitzPatrick Lectures he gave to the Royal College of Physicians of London, he shows that, as contrasted with internal medicine, the surgical descriptions and procedures were more direct, definite, and accurate. In a recent article Mr. A. Don has taken up the theme from the more limited aspect of Roman surgery in the first century,¹ and for this purpose relies mainly on the works of the encyclopedist Celsus, who has been called "the Roman Hippocrates," and also, though with less laudatory intent, "Hippocrates's ape." Celsus also wrote on rhetoric, philosophy, law, and the art of war; but as he was a Roman citizen, and probably a patrician, it would have been beneath his dignity to have practised the healing art, which was in the hands of Greeks and slaves. According to Mr. Don, however, a critical examination of his works proves not only how well versed in surgery he was but that he must have watched very closely the operations of others and occasionally operated himself. Celsus divided medicine into pharmacology, dietetics, and surgery, and remarked, "surgery does not reject the other branches, but it effects most by the hand." Physicians had a broader field of, at any rate superficial, activity at this period than now, for it included inflammation, ulcers, and in fact all diseases except those in which the surgeon had to make the first wound or where manual operation would be more efficacious, and lastly diseases and injuries of bones. The physicians were the bleeders, blood-letting being a reputed panacea, sometimes beneficial, seldom dangerous, and always lucrative. Mr. Don brings forward examples to show that surgical practice in the first century was often on the lines now approved; thus the Roman method of extracting weapons and other foreign bodies was practically the same as our own, and cysts were excised without opening the sac if possible; the tonsils were enucleated according to the method employed in our best clinics; catheterization was performed in a manner that would do credit to a modern professor. After pointing out that trephining was practised in almost all fractures of the vault, the dura mater being left intact if possible, as was the procedure in the recent war, Mr. Don remarks: "Celsus would have made a model surgical specialist in a team 'head' hospital in France; he advocated trephining on the opposite side in *contrecoup*, and was well acquainted with hernia of the brain and with depressed fracture." Only a few of the more common dislocations are well described by Celsus, who generally follows the teaching of Hippocrates in this respect, though he differs from the Father of Medicine in recommending that no attempt should be made to reduce dislocations of the spine, on the ground that in complete dislocation the cord will have been severed and the nerves torn, and in incomplete dislocation the bones will not stay in position when reduced. His symptomatology of dislocations of the head of the femur is nearly as accurate and full as the well-known signs given by Sir Astley Cooper.

THE NEW SCHOOL OF HYGIENE.

IN the JOURNAL on February 25th (p. 325) and on March 4th (p. 351) we announced and discussed the gift of the Rockefeller Foundation of two million dollars (approximately £400,000) for the establishment and equipment of an institute or school of hygiene in London. The Minister of Health, in informing the House of Commons of the acceptance of this generous offer, said that the Government would provide the annual expenditure for staff and maintenance, estimated at some £25,000 a year. Sir Alfred Mond added that he would set up a committee to advise him on the preliminary steps to be taken in regard to the site and planning of the school of hygiene. The Ministry of Health now announces the composition of this committee. The chairman is Sir Arthur Robinson, First Secretary of the Ministry; the other members are Sir Frank Baines, Director of Works, H.M. Office of Works; Dr. H. H. Dale, F.R.S., Head of the Department of Biochemistry and Pharmacology under the Medical Research Council; Sir Walter Fletcher, M.D., F.R.S., Secretary of the Medical Research Council; Major General Sir William

¹ A. Don, *Caledonian Med. Journ.*, Glasgow, 1922, xi, 350-351.

Leishman, F.R.S., Director of Pathology, Army Medical Service; Sir George Nowman, M.D., Chief Medical Officer of the Ministry of Health and the Board of Education; Sir Cooper Perry, M.D., Principal Officer of the University of London; and Sir Herbert J. Read, Assistant Under-Secretary of the Colonial Office. The secretary of the Committee is Dr. H. Meredith Richards of the Ministry of Health.

PROHIBITION AND THE MEDICAL PROFESSION.

SOME time ago the *Journal of the American Medical Association* issued a set of questions on the use of alcohol in the practice of medicine to 53,000 medical practitioners (37 per cent. of the practitioners in the United States), and answers were received from 31,115, or 58 per cent.; 25,819, or 83 per cent., of the medical men were general practitioners, 2,401 were engaged in surgical specialities, and 2,825 in non-surgical specialities. The total number who expressed an opinion on the question whether whisky was necessary in the treatment of disease was 30,843; of these, 15,625, or 51 per cent., answered in the affirmative, and 15,218, or 49 per cent., in the negative. The question whether beer was a necessary therapeutic agent in the practice of medicine was answered in the negative by 74 per cent., and in the affirmative by 26 per cent. To the question whether wine was a necessary therapeutic agent the answer was in the negative in 68 per cent., and in the affirmative in 32 per cent. The North Atlantic and South Atlantic States gave a majority affirming that whisky was necessary as a therapeutic agent, while in the North Central, South Central, and Western States the majority thought otherwise. Thirty-two of the fifty largest cities affirmed that whisky was necessary as a therapeutic agent, seven gave a majority vote favouring wine, and only two gave a majority vote favouring beer. Of the medical practitioners who replied, 22 per cent. stated that instances had actually occurred in their own practices in which unnecessary suffering or death had resulted from the enforcement of prohibition laws, but the remainder stated that they had not seen such cases. The reply to the question whether medical men should be restricted in prescribing whisky, beer, and wine was in the affirmative in 58 per cent., and 42 per cent. believed that there should be no restrictions; practitioners in the rural districts were more inclined to favour restrictions than those in the cities. An editorial note suggests that the inquiry has definitely shown that the present regulations in the United States governing the use of alcoholic beverages are not satisfactory. Many practitioners who were convinced that these drugs were not necessary therapeutically were emphatic in stating that others who believed them necessary were entitled to have their views respected, and were warranted in their efforts to have the drugs made available without incurring the odium attaching under the present regulations.

THE EFFECT OF ALCOHOL ON GASTRIC DIGESTION.

This would at first sight appear to be a well-worn line of research, and indeed this is shown by the list of 182 references attached to Aksel O. Haneborg's thesis in English on the effects of alcohol upon digestion in the stomach,¹ which contains the results of work carried out in the Physiological Institute of the University of Christiania and in the hospitals of that city. Much of the physiological work in the past has been carried out with commercial pepsin *in vitro*, and hence Haneborg's experiments performed on healthy persons and patients with various disorders approach much more closely to those of ordinary practice. These show that 75 per cent. of alcohol, taken in the proportion of 0.5 c.cm. per kilo of body weight, is absorbed from the stomach in half an hour, and that after the lapse of an hour from the time of taking it, alcohol has practically disappeared from the stomach. Very little alcohol when taken in this amount passes into the small intestine. The alcohol undergoes combustion within

three or four hours, and only 0.1 to 0.5 per cent. of that consumed is excreted in the urine. It is rather surprising to find that chronic gastritis does not interfere with the absorption of alcohol from the stomach. By giving alcohol in test meals on patients with gastric disorders an attempt was made to determine the indications and contraindications for alcohol in these diseases; but as the secretion of gastric juice depends on a number of factors, the effects of which at any given moment it is difficult to control, final conclusions require a very large series of observations. Alcohol increases the secretion of gastric juice probably by its action on the nervous system after absorption, but the psychological effect of alcoholic drinks, produced by sight, smell, and taste, appears to be less important than might be expected. There is a difference between the action of pure alcohol, on the one hand, and of beer and wine, on the other; thus, beer and wine retard digestion because their salts neutralize the free hydrochloric acid; but later, when absorption into the blood has occurred, there is an increased secretion of gastric juice, as in the case of pure alcohol. Indirectly, by increasing the amount of hydrochloric acid, alcohol in certain cases increases the rate at which the stomach is emptied. In and ulcer alcohol is clearly contraindicated, with deficient secretion it is of use, though not in complete achylia. After the age of 50 years there is deficiency of free HCl in 30 to 50 per cent. of ordinary persons, and though with suitable food no symptoms of discomfort should arise, an unsuitable diet readily has this effect, which may be alleviated by alcohol. Haneborg, however, considers that his observations tend to lower the former reputation of alcohol as a stomachic, and insists that there should never be more than 10 per cent. of alcohol in the gastric contents, otherwise the pepsin is affected. This is surely so large a proportion that it can seldom be reached if the alcohol be taken at a meal. In carcinoma of the stomach alcohol may relieve pain by its narcotic action, and retard fermentation in patients with pyloric obstruction; better results, he says, are obtained with whisky and brandy than with wines and beer.

SKIN EFFECTS OF ULTRA-VIOLET AND RADIUM RADIATION.

IN a communication to the Röntgen Society on March 7th Mr. L. H. Clark and Mr. B. D. Watters, of the Physics Department of the Middlesex Hospital, gave the comparative results of exposures of the skin to ultra-violet radiation and to the beta rays of radium. The object of the experiment was to find out whether there was any connexion between the effect of these radiations on the skin and the photographic action and ionizing effects to which they also give rise. One interesting fact revealed in the course of the experiments was that the erythema resulting from exposure to ultra-violet radiation can be made to disappear completely by simply stretching the irradiated skin. When the tension upon the skin is relaxed the erythema reappears. Such an action can be shown with ease on the day of irradiation, though later on it is not so clear. It was also discovered within what range of wave lengths of ultra-violet the skin reaction to exposure is most intense, and from these studies it would appear that very considerable portions of the radiation emitted by arcs of mercury, tungsten, and iron are relatively ineffective in their action upon the skin. It is the more refrangible ultra-violet radiations which are most effective in exciting skin reaction, and this fact suggests the need for care when taking photographic action to indicate the skin response. A tint method for indicating the skin reaction, which is based upon the photographic action of the whole radiation from a given source of ultra-violet light, is liable to fail, although the tint method is quite efficient in the case of beta radiation. The photographic plate, sensitive as it is to the whole range of visible light and ultra-violet radiations, fails to discriminate between those radiations which excite an erythema reaction and those which are inactive so far as the skin is concerned. It is clear that there is no accurate method of measuring the therapeutic activity of the ultra-

¹ The Effects of Alcohol upon Digestion in the Stomach. By Aksel O. Haneborg. *Acta Medica Scandinavica*, Supplementum I. Christiania: Haneborg and Son, 1921. (Pp. 128. Price not stated.)

violet radiations from a quartz mercury arc. Neither the photographic nor the ionization method is trustworthy here, although both may be applied in measuring the action of the beta rays of radium. Another point noted by the authors was that the time which elapsed between irradiation and the appearance of the reaction was much shorter in the case of exposures to the mercury arc than in the case of exposures to beta rays. Some accurate method of measuring the efficiency of sources of ultra-violet radiation when used for clinical purposes is clearly called for.

THE GROWTH OF THE HUMAN FACE.

THE paper entitled "A contribution to the mechanism of growth of the human face," a report of which we publish on another page, is of more than passing interest. The desire of the authors (Sir Arthur Keith and Mr. George Campion) was to furnish a description of the normal growth of the human face which should serve as a basis for the orthodontist to work from, and they have given an account which, it not final (and it is not claimed as such by the authors), at least merits the close attention of all anatomists, and must always remain a conspicuous contribution to the literature of the subject. We know of no other work in this line which compares with it. The method of superposing sectional plans in order to compare growing with adult skulls is also employed by Sir Arthur Keith in this paper to compare modern with neolithic faces, and normal with "adenoid" and acromegalic faces. He concludes that the neolithic face was longer than that of the modern well-developed Englishman, which in turn is both longer and broader than the adenoid face. He also shows that the acromegalic face increases by a process of true growth. The paper thus becomes interesting not only to the anatomist, but to the biologist and to a large number of specialists beyond the orthodontists to whom it was originally presented. The British Society for the Study of Orthodontics is to be congratulated on having secured so valuable a communication, and we trust it will make its reprints available to all who are interested in the subject.

THE IMPORTANCE OF CARBOHYDRATES.

IF prehistoric ages can be described as stone or bronze, the present age, with even more justification, might be called the carbohydrate age, for not only do men rely upon carbohydrates for food and for a large part of their clothing, but they use nitro-cellulose to make war, and disseminate their news upon a web of vegetable fibre, and in both instances they are dependent upon the carbohydrate productiveness of plants. Dr. P. Haas, lecturer on plant chemistry at University College, London, in an address to the Pharmaceutical Society on March 9th on the importance of carbohydrates in present-day economy, described much recent work which has been done with the object of increasing the carbohydrate activity of the vegetable kingdom. In Germany attempts have been made to stimulate carbohydrate production by increasing the carbon dioxide in the atmosphere, either by applying waste fuel gas to the plants in hothouses (the gas being freed from poisonous constituents) or by assisting fermentation of the fertilizer or manure strewn on the ground. It is said that a 50 per cent. increase in the yield of tomatoes and beetroot has been obtained by these methods. In the case of sugars, the lecturer referred to recent attempts to place the beet industry, both in this country and on the Continent, on an economic footing; so far as starches are concerned, much has been done to render both wheat and potatoes immune from the diseases to which they are liable, and to cross wheat so as to secure a greater yield of flour; while cellulose, the most widely distributed organic compound on the planet, although of no use as a food material for human beings, has lately had its food value for herbivorous animals increased, for the treatment of straw by alkali has made it much more digestible to horses. Another great field for carbohydrate economy is timber. Dr. Haas mentioned that in this country every year

our timber consumption represents a forest equal in area to the counties of London and Middlesex, and that one of our daily newspapers enters up two acres of mature pine forest every day. There is practically only one carbohydrate—lactose—which man can obtain from the animal kingdom; for all the rest he is dependent on plants.

MEDICAL SOCIETY OF LONDON.

A social guide-book to the medical institutions of England would certainly place three asterisks, in the manner of Brediker, against the annual dinner of the Medical Society of London. The Society was founded in 1773, "to give the practitioners of the healing art frequent opportunities of meeting together and conferring with each other concerning any difficult or uncommon cases which may have occurred, or communicating any new discoveries in medicine which have been made either at home or abroad." Another object always kept in view has been the promotion of good-fellowship among the members. The 149th anniversary dinner held on March 8th at the Warnccliffe Rooms, with the President, Mr. James Berry, F.R.C.S., in the chair, was in line with its many predecessors, and as usual the Society entertained a number of distinguished guests. The toast of prosperity to the Medical Society of London was proposed by Sir Humphry Rolleston, who recalled to his hearers the two patron saints of the Society—John Coakley Lettsom and his friend, John Fothergill—and James Sims, its President for twenty-two years. He congratulated the Society on having now as President so eminent a man as Mr. Berry. The President, in his reply, gave some entertaining extracts from old minute books, with appropriate digressions. In submitting the health of kindred societies and guests, Mr. V. Warren Low introduced, with a light touch, the names of the principal visitors: Sir Anthony Bowlby, F.R.C.S., Sir Dyce Duckworth, and Lord Knutsford, Chairman of the Research Defence Society; the Presidents of the Medical Psychological Association (Dr. Hubert Boud), the Harveian Society (Sir William Wilcock), the Medical-Legal Society (Lord Justice Atkin), the West London Medical-Chirurgical Society (Sir Lenthal Cheate), and the Chelsea Clinical Society (Dr. David Barclay); also Surgeon Vice-Admiral Sir Robert Hill, Medical Director-General R.N., Lieutenant-General Sir John Goodwin, D.G. Army Medical Services, and Air Commodore David Munro, Medical Administrator R.A.F. The toast was responded to by Sir Robert Hill and Sir Richard Atkin, and the President's health was proposed in warm terms by Dr. Walter Carr.

THE King, by the advice of his Privy Council, has appointed Sir Nestor Tirard, M.D., F.R.C.P., to be for five years a member of the General Medical Council, in place of Mr. Norman G. Bennett, M.B., B.Ch., L.D.S., resigned.

MR. T. EASTHAM, M.B., Ch.B., lately a member of the Northern Circuit, has been appointed by the King, on the recommendation of the Lord Chancellor, a King's Counsel. On behalf of the medical profession we offer him congratulations on this honour.

A PSYCHIATRIC congress will be held in Paris on May 30th and 31st, to commemorate the centenary of the thesis in which Bayle, in 1822, for the first time defined general paralysis. The congress will be international in character, and Dr. Toulon will be president. A banquet will be held on May 31st, at which French alienists will entertain their colleagues from allied and friendly countries. Further information may be obtained from M. Raymond Mallet, 284, Boulevard Saint-Germain, Paris.

THE thirty-third congress of the Royal Sanitary Institute will be held at Bournemouth from July 24th to 29th. Delegates from Australia, Tasmania, Canada, South Africa, Singapore, and Ceylon have already been appointed, as well as from China and Denmark. The Lord Mayor of London is honorary president of the Conference of Representatives of Sanitary Authorities, and the Lady Mayoress of the Section of Personal and Domestic Hygiene.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

The Orthopaedic Hospital, Shepherd's Bush.

SIR HENRY FOREMAN asked, on March 9th, whether the Minister of Pensions was aware that the time for vacating the Orthopaedic Hospital at Shepherd's Bush was drawing near; if he could report whether fresh negotiations had been entered into with the guardians on the question of rent; if not, was he prepared to facilitate those negotiations by withdrawing the expression "blackmail" which he used in reply to a question on this subject recently. Major Tryon said that Mr. Macpherson was willing to withdraw any expression he had used, provided he was assured that the State would have the opportunity of continuing to maintain its disabled men in this hospital at a fair and reasonable rent. He was still prepared to stand by the offer of an increased rent which he had already made, and in order to avoid any possible doubt he was so informing the guardians. Sir H. Harris inquired whether disabled men would suffer if this hospital were closed. Major Tryon answered that according to his information the alternative hospital was a very good hospital, and in better surroundings. He was so informed by the highest medical authority the Department had, but they were prepared to allow the patients to remain on reasonable terms. The Ministry had been paying £8,000 a year since they took over the hospital up to the end of last year. They were now willing to give £12,000, but the guardians were asking £14,000. Captain Bowyer asked whether the question had been considered of letting the matter go to arbitration. Major Tryon responded that the simple solution was for the guardians to accept the reasonable and largely increased rent offered to them. Colonel Wedgwood put it to the Minister that the alternative hospital was extremely unsuitable for those who had to attend for treatment. Major Tryon said that was a perfectly good point. It was obvious that provision would have to be made for the out-patients, but he had found on inspecting both this hospital and the hospital at Roehampton that the Roehampton authorities would regard the removal from Shepherd's Bush as bringing out-patients nearer to the work being done at Roehampton. Questioned by Lady Astor whether the equipment was not far better than in any other, Major Tryon said that the equipment could be moved.

Ministry of Health.

Supplementary Votes.

On the vote on account for £148,300,000 for Civil Service and Revenue Departments, on March 14th, Mr. Clynes moved a reduction of the vote for the Ministry of Health in respect of housing; he did this to ascertain the further policy and administrative action of the Government in this matter. Mr. Rhys Davies afterwards turned the debate from questions of housing to those more immediately of health.

Mr. Davies complained of a paragraph in Cirenlar 257, which was issued last November by the Minister, wherein he said that local authorities should require a contribution towards the cost of residential treatment of persons suffering from tuberculosis. Very few authorities had adopted this suggestion, which he held to be a violation of pledges given to persons suffering from consumption. The issue of the Cirenlar was without precedent, because, when the Insurance Act came into operation, insured persons were entitled by law to receive sanatorium treatment under it free of charge, because they paid for it in their contributions. To require that an insured person who was consumptive should pay as a condition of entering a sanatorium would act as a deterrent against entry.

Mr. G. H. Roberts called attention to reduction in the Estimates under the heading of "Grant for the Welfare of the Blind," the sum being £20,000 less than last year's estimate. He thought that any reduction in this work would be false economy and contrary to humane ideals. He mentioned that there were 34,894 blind persons under the control of the Ministry of Health, and of these 17,228 were returned as unemployable. He urged that even in these days of stringency we should develop our plans for the treatment of the blind. Of the total number mentioned, 1,383 were mentally defective, and their case was particularly hard. He was presiding over a committee which was inquiring into the causes of blindness and defective vision, and there it had been ascertained that a good deal of blindness was preventable, and this was an additional reason for his plea for greater development in this direction.

Mr. Evans, after relating the work done by the Welsh National Memorial Association for the promotion of health, and especially to prevent the spread of tuberculosis, said that the association was in the fortunate position of being able to acquire a house was called St. Bride's, in Pembrokeshire, the residence of Lord Kensington, who had spent £100,000 on this property. He was willing to sell it to the association for a very small sum—about £10,000—and with the resources that the association had they could provide beds at an average cost of £220, whereas, taking

hospitals in the country generally, the cost worked out at £600 a bed. But because they had acted in a businesslike way and had not pushed forward the matter earlier, they were threatened with the loss of any grant at all from the Government. He appealed that they should be allowed the small sum they asked.

Mr. Godfrey Locker-Lampson criticized the reappointment a fortnight ago of the Chairman of the Welsh Board of Health which had been made, notwithstanding the recommendation of the Geddes Committee that the Welsh Board should be abolished. Referring to the recommendation of the Geddes Committee that unemployment and health machinery should be amalgamated, Mr. Locker-Lampson said he was aware that a Departmental Committee had been appointed to consider the subject. But the important point was this: there were only a few days in which to make the decision. Unemployment and Health Insurance cards would have to be printed in a few weeks at latest, because they had to be dispatched by the end of July.

The Minister's Reply.

Sir Alfred Mond, replying to various speeches, said that the question of tuberculosis administration was occupying the very serious attention of his department. A careful investigation was being made of the money spent by local authorities. He had been much struck by the inequality of expenditure in various localities for apparently similar services. He quite sympathized with the statements made at various times as to the value of after-care treatment. If there were more funds at disposal that would be a very useful matter in which to employ them, but at present the department could only keep going those services which were already running. He thought he could promise that in spite of reductions no health service would go back. The amalgamation of Health Insurance and Unemployment Insurance was a subject full of technical difficulties, but he believed that the Committee would be able to arrive at a solution.

Sir Alfred Mond next defended the continuance for the present of the Welsh Board of Health and said that in any case, if the work were ultimately transferred to London, the Chairman would have to be transferred with it, and therefore the reappointment was sound. With regard to the grant to the blind he said it had been found that the estimates for 1921-22 were not expended, and they were taken as the basis for the coming year, the question of what else might be necessary being deferred pending the report of the committee over which Mr. Roberts presided. He was going personally into the appeal for the grant for a tuberculosis hospital in P. to be by Mr. Evans, and so far as he had any glad to see the work undertaken. In reference to housing he claimed that the Ministry were carrying out a large programme and believed that with a little patience they could induce private enterprise to come in again. The price for a cottage had been brought down to £400. Coming to the question of slums the Minister mentioned that when we had 400,000 empty houses in the country the figures for overcrowding were about the same as now: that demonstrated that this was not merely a question of providing houses. Indeed, they all knew that a certain number of people would not move out of a slum if provided with fresh houses. Sometimes this was because of convenience of position; sometimes because people did not care what kind of house they lived in; and sometimes because they had got so used to their surroundings they did not realize how bad they were. Slums would not be got rid of solely by providing houses. Two things of the utmost importance that could be done were being done. Local authorities should use their powers for the repair of individual houses. The reports of medical officers of health for 1920 showed what could be done under statutory powers. Over 1,000,000 houses had been inspected and notices for repair had resulted in the repair of 218 houses by owners and 1,900 by local authorities. The other step being taken was for wholesale demolition and clearing where no other course was possible.

Mr. Myers drew attention to the extensive sale in this country of milk below the standard quality. He referred especially to separated milk. He regretted to find in the estimate a reduction for the coming year of £359,000 under the heading of tuberculosis. There was a new item of £175,000 for the provision of sanatoriums, but that meant a net reduction of a little under £200,000. The country, in his opinion, was not getting value for its expenditure on tuberculosis, partly because the consumptive person was not got hold of early enough. There was actually a greater proportion of deaths from tuberculosis in proportion to the number notified in 1920 than was the case in 1915. He agreed with a remark made by Lady Astor earlier that overcrowding had a great deal to do with consumption.

The Debate Continued.

Dr. F. E. Fremantle, in an admirable examination of the housing problem, drew attention to the value of "zoning" for industrial centres as tried in New York. In regard to the prevention of venereal disease, he expressed the hope that the Minister might be able to reconcile the two voluntary associations to work together on common lines. Speaking of medical officers of health he deprecated the appointment of whole-time men when there were local men specially suited from knowledge of conditions and local advantages. He urged that Poor Law officers in their own domestic work should be associated with the health side of the Ministry of Health. Why the Poor Law medical officer was not, as he should be, the foundation of public health was because hitherto the ordinary education of the ordinary medical man had not included work on public health. The curriculum was ordained by the General Medical Council, and it could well rearrange the

curriculum to meet needs. The subject was now in the melting pot, and he suggested that the Minister of Health should offer advice to the Council in this regard.

Dr. N. Raw regretted that there had been some reduction in the amount to be devoted to the treatment of tuberculosis. The sum which the Minister had put down represented a little more than £1 a head a year in the treatment of this great disease, over a million persons being affected with it in Great Britain. He agreed, of course, that the question of housing was at the very root of the prevention of tuberculosis. He did not agree, however, with some members who argued that the money now being spent on the treatment of tuberculosis was wasted; but he agreed that a great amount of effort was wasted because the work was not continued. It was useless to devote several months to treatment in a sanatorium and allow the man to go home to living conditions in which he was almost certain to relapse. Therefore he urged the Minister to consider the importance of training in the sanatoriums and of providing tuberculosis colonies in which a man could be taught an occupation and remain.

Sir Watson Cheyne touched on the importance of preventive work in regard to tuberculosis. He referred in the first place to the need for segregation, and secondly to the danger of infection from tuberculous milk. He believed that about 60 per cent. of the various forms of disease in children were due to infection from tuberculous cattle by means of milk, and he had never been able to understand why stronger measures were not in force against this source of infection. He had received a circular which led him to fear an agitation was being started to prevent the Minister from bringing in another Milk Bill. The circular stated that it was understood that the Minister had an agreed bill. He did not think there would be an agreed bill of any use. The Government with their large majority should have no trouble in passing any measure they liked, but he was not sure that it would not be well for them if they could not arrange to be defeated on such a measure. Then they could go to the country on a "Save the Children" issue.

Lord Robert Cecil reiterated the importance of good housing for the prevention of tuberculosis.

Sir Alfred Mond, in his final reply, said that the sale of skim milk as whole milk (to which Mr. Myers had referred) was nothing less than a robbery of the people, and he cited the section of the Food and Drugs Act, 1871, under which it could be dealt with. He agreed with Sir Watson Cheyne that it was most undesirable that tuberculous milk should be sold at all, but the question of how to stop the sale was not quite so easy. There was the problem of the farmer, who might be in a difficult position.

Coming next to the matter of venereal disease, the Minister said representations had been made to him from more than one quarter whether something could not be done to get the societies dealing with this subject to combine. Nothing would give him greater pleasure than to bring this about; but it was a subject giving rise to considerable controversy. He had tried to obtain the assistance of the Medical Council and of Lord Dawson to get together a body of medical men who would look at this question from a medical point of view and advise him. He could not overlook the fact that there was also a moral aspect, and on that point he would never be a party to some of the propaganda which was being carried on. Sir Alfred Mond explained that the reason he had issued a circular of inquiry as to supplying disinfectants to nursing mothers instead of milk was that some very competent medical authorities thought it would be more valuable.

On a division 52 members voted for the reduction of the vote and 156 against.

Licences for Morphine.—Mr. Gilbert asked, on March 9th, what was the form of licence issued under the Dangerous Drugs Act, 1920, permitting the manufacture of morphine in Great Britain and for some further particulars as to its manufacture. Mr. Shortt said that the form was an authorization to carry on the manufacture of morphine at certain premises specified in the licence, and subject to certain conditions. The conditions were not necessarily the same in each case, but, in general, they provided for adequate supervision, exclusion of unauthorized persons, keeping of records of production, and the like. The number of firms and premises licensed was three. The amount of British-made morphine exported during 1921, as shown in the Customs Returns, was 81,093 oz., but this did not include the amount exported through the parcels post. The total amount of morphine licensed for export, including export by post, was 112,681 oz. Morphine was exported to all parts of the world, but over one-half of the amounts shown in the Customs returns went to France. Other countries which received more than 5,000 oz. were Sweden, Belgium, and Canada.

Diphtheria in London.—Sir A. Mond, on March 9th, stated that there was still considerable prevalence of diphtheria in the metropolis, the number of cases notified during each week of the present year being over 300. This, however, represented a considerable improvement as compared with the last three months of 1921.

Tuberculosis Statistics.—Sir Alfred Mond, on March 8th, said he could not accede to a request by Mr. Rhys Davies to obtain from the local authorities detailed statements of the number of persons, male and female separately, suffering from various forms of consumption in England, Scotland, and Wales. He appreciated that the information could be taken from the reports of the medical officers, but remarked that it would mean a great deal of work.

Ear Affections in Pensioners.—In answer to Mr. Alfred T. Davies, Mr. Macpherson, on March 8th, said ear affections were pensionable under the Royal Warrant according to the degree of disablement found to exist, the rate of 70 per cent. being fixed for complete

deafness. In addition, skilled medical and surgical treatment appropriate to the individual circumstances was provided in ear hospitals or at special aural clinics established by the Pensions Ministry. At the present time approximately 5,500 men were receiving treatment for some form of aural disease, and these who were prevented by their treatment from working were drawing the usual allowances. Facilities for acquiring facility in lip-reading were also provided in suitable cases.

Clearing Houses and Pensions Clinics.—Mr. Alfred T. Davies asked, on March 8th, on what date it was hoped to establish clearing houses for patients seeking admission to hospitals; when the new clinics would be established and at work; and what arrangements had been made for these clearing houses and clinics. Mr. Macpherson said that the clearing-house system had been in actual working operation in all regions for some time past. It was proposed to establish 163 general clinics, 55 of which were at present in process of being set up in some of the larger towns. The remainder would be proceeded with as rapidly as possible.

Liquor Traffic: State Management.—Mr. Shortt announced, on March 8th, on inquiry by Sir A. Holbrook, that he had appointed an Advisory Council at the Home Office to deal with questions of the State management of the liquor traffic. It consisted of the Secretary for Scotland and himself, the two departmental representatives (namely, Sir John Pedder and Mr. T. J. Rose), and four others, Mr. Waters-Butler, Mr. S. E. Neville, Sir John Sykes, and Sir William Towle.

Dentists Act Regulations.—Mr. Seddon, on March 8th, moved for the annulment of the Dentists Act Regulations, which, according to the terms of the measure, had been placed on the table of the House of Commons on February 7th. He alleged that ex-service men had a grievance in the restriction of enrolment on the Register. Mr. Acland, who is Chairman of the Dental Board, explained the position. The Act said that to be entitled to admission to the Register persons ought to have practised five out of the last seven years; but the Board were also directed to take special thought and care for ex-service men if satisfied that they could safely practise. The Act contemplated that there should be some continuity of practice, but where owing to war service that continuity had been broken, some allowance should be made. Therefore the Board resolved that if a man had practised for five years, partly before and partly after war service, even though the period were not in seven years, he should be admitted automatically. Where an ex-service man had not completed five years' practice, regard must be had to the question whether he was qualified to serve the public. Unless the question of his having practised dentistry during the war arose, the Board held that he must submit to one of the examinations. No fee would be charged. In judging practice of the profession during the war the difficulties were great. Mr. Acland instanced claims by men who had carried a pair of forceps and extracted teeth from men suffering in their squadron. The conclusion reached was that unless a man had some official engagement during the war, such services as he had rendered could not be taken into account. Coming next to the complaint as to the fee of £5 charged for registration annually, he pointed out that the Board were required by the Act to raise money for dental education and research. If after a few years they had enough money to give sufficient help for education and scholarships, it might well be possible to reduce the fee to £3 or even to £2. There had not been a single protest by a dentist. Sir A. Mond, replying for the Government, said that Mr. Acland had done, and men received was between £35,000 and of a couple of years the end of review. Mr. Acland pointed out that Mr. Seddon, after regretting that he had not obtained the explanation without raising the matter in the House, as he now recognized he could have done, withdrew his motion.

Leprosy in Great Britain.—Replying to Sir C. Yates, on March 8th, Sir A. Mond said that the question of making leprosy notifiable in this country had been carefully considered from time to time, but he was not satisfied that there was sufficient justification for this course to be taken.

Deaths from Starvation.—Mr. Robert Richardson asked, on March 8th, in what way the returns of deaths from starvation made before 1919 were unsatisfactory; whether they could be made satisfactory; whether, in fact, the Local Government Board up to 1919 did, on receipt of information from the coroner of a death from starvation or accelerated by privation, call upon the guardians for information; whether during the three years 1919-21 the usual communications had been addressed to the coroners; and if not, what steps had been taken to see whether such deaths might have been prevented by more effective Poor Law administration. He further wished to know whether any inquiry of the guardians was made by the Registrar-General. Sir A. Mond said that the selection of cases for inclusion in the old returns depended upon the terms of the verdict of the coroners' juries and on the classification of those verdicts by the several coroners. No uniform or scientific principle was followed; the return was consequently both useless and misleading. He could not see that any useful purpose could be served by a revival of the return even in an improved form. The general inspectors of the Ministry of Health were instructed to take immediate steps to investigate any suggestion made at an inquest or otherwise that a death had been due to some fault in Poor Law administration. This practice, which was instituted before 1919 and still operated, was far more effective than any steps that could have been taken on an annual return. The Registrar-General was not concerned to make any inquiry.

Paris.

(From our Correspondent.)

SCHOOL CHILDREN.

"And they can't go on strike!" These words of pity and of revolt resounded the other day through the conservative halls of our Academy of Medicine. They were the concluding words of Dr. Linossier's denouncement of the present condition of the schools; in the name of hygiene and of common sense he called upon the Academy to protect the school children of France.

Dr. Linossier, the type himself of an indefatigable worker, found himself one day called upon to cultivate what Victor Hugo called the "art of being a grandfather." On leaving his laboratory he bent over the table of his grandson, a child of 9 years, and was horrified to find this boy, under the pretext of natural history (department of "carcinology"), trying to commit to memory the terminology of the different classes of crustaceans: "*crustacés planctoniques, néctoniques et benthiques*"; the weather was fine, and there was a football sleeping in the garden! The grandfather made inquiries, and found that the child worked nine and a half hours each day. His school gave him twenty-four hours of instruction each week, of which gymnastics occupied one hour—that is to say, he had twenty-three hours of mental exercise against one hour of muscular exercise. Since the pedagogues so seriously misunderstood the hygiene of children, it was time for the doctors to intervene. This is the reason why the Academy of Medicine was called upon to discuss, on January 17th and on February 14th, the courses of public instruction in our country.

You may well say that the quarrel is of old standing, has always been with us, recurring periodically on the order of the day. The last reform ended in an attempt to draw a distinction between classical instruction, including Latin, and scientific instruction (*sic*), with two modern languages obligatory. Greek was an optional language, but few took up the option. The results, however, were not brilliant. Recently an attempt was made to reconcile the humanists and the scientists and bring the quarrel to an end; as always happens, it was the schoolboy who ran the risk of having to pay the cost of the reconciliation. The humanists threw upon his back the extra load of a modern language, and the scientists benevolently admitted that Latin should be piled on top of his already badly balanced burden. At the present moment the Superior Council of Public Instruction is deliberating. It is a council of specialists, with immutable traditions, already too far from their childhood to remember it. For one of them there could be no complete man without a knowledge of Cicero's moralizings, for another knowledge of the phenols is indispensable before life can be begun. The result is that the brains of our children are "forced" as flowers in a hothouse. Brilliant flowers, but fragile ones. In the open air they are disappointing.

Happily the child has a wonderful gift of inattention, which allows him to shake himself free from all intellectual harness. He is believed to be in the class, but he is playing truant. His imagination laughs at regulations which impose the double torture of silence and of immobility. Inhibition is his intellectual defence. Oh, blessed and salutary idleness! It is intriguing to find our academicians upholding a similar thesis, which they set out in the following resolution: The time required to be given to classes and study ought not to exceed eight hours a day for children under 14 years of age. (In a secondary school—*lycée*—in Paris at the present moment the elder pupils have thirteen hours' work each day. The headmaster has lengthened the hours of sleep to nine. Two hours are left for meals and for exercise. The régime for prisoners is healthier than this.)

The Academy asks for organized games. This is difficult in the overcrowded schools of Paris, where the school yards are small and cannot be enlarged, and the majority of pupils are small and cannot be awakened of enthusiasm by proxy. And yet what an awakening of enthusiasm for sport there is among our young people! Besides games there is the teaching of manual work, carpentry, locksmith's work, and so on. In the present state of society the hour seems to have struck for training of this sort.

All this demands time. But an authority so eminent as the director of the Institut Pasteur, Dr. Roux, has declared himself in favour of the suppression of afternoon classes. The classes should be more homogeneous, and should consist of

thirty pupils only, chosen according to their abilities. Those whose negative gifts keep back their schoolfellows would be rapidly eliminated; very often if sent to a technical school they will find their bent. Finally, in regard to method, the Academy proposes that less attention should be paid to the memory of the child, and puts forward as its own the suggestion of that pioneer of genius, Jean Jacques Rousseau: "*Que l'enfant invente la Science.*"

Such are the results of the recent deliberations of our highest medical authorities; they are attracting the attention of the whole country. There is nothing wiser or more urgent. It is indeed a duty to pass on the torch to the young, yet how necessary is it not to burn our fingers. It is essential to decide against that *boutade* of a cynic when a mother was worrying: "The little one is too precocious for his age, too intelligent. . . ." "Send him to school," said the father.

England and Wales.

THE LEEDS GENERAL INFIRMARY.

The statistical tables of the Leeds Infirmary for the year ending December 31st, 1921, show an increase in the amount of work carried on at this great charity and school. The number of patients treated in the wards as in-patients was 9,702, an increase of 222 over the previous year. The daily average of in-patients was 518; of this 87 represented the daily average at the two convalescent hospitals at Cookridge. This increase of work has only been rendered possible by the opening of the new wards. There yet remains one large ward which is approaching the completion of its modernizing, a process to which all the original wards have been subjected during the last few years, but it must depend on the state of the funds of the institution whether this can be opened in the near future. The average stay of each patient in the infirmary was sixteen days; it would not be possible for this number to be kept so low were it not for the use which is made of the semi-convalescent hospitals at Cookridge which enables the treatment to be carried out during that period when, after operations, patients require skilled attention and are not ready for ordinary convalescent treatment. The number of deaths at the hospital, including three at the semi-convalescent hospitals, was 680; of these 217 occurred within forty-eight hours of admission; if these are deducted the percentage mortality of cases admitted to the infirmary works out at 4.9. The out-patient figures show in some cases an increase and in others a decrease; thus there were 1,401 fewer casualties dealt with, the figures being 15,969 for 1920 and 14,568 for 1921; probably this must be taken in connexion with the amount of unemployment which prevails; ordinary out-patients show an increase of 683, the numbers being for each year between twenty and twenty-one thousand. The number of cases attended to in the out-patient maternity department shows a diminution in respect of the transference of this work to the Leeds Maternity Hospital and next year will show no figure referring to a maternity department, which has now been wholly transferred to the Maternity Hospital. There has been some decrease in the number of cases of venereal disease, the figures being 2,599 for 1920, and 1,804 for 1921.

In mentioning these figures one cannot but reflect upon the immense amount of work which has been done by the infirmary since the present building was opened by the late King Edward, then the Prince of Wales, in the year 1868; 415,669 patients have been treated in the wards, irrespective of about 6,000 soldiers treated during the great war. The finances of the infirmary are a source of much anxiety to the board, and have been for many years. It is earnestly to be hoped that none of the aspirations of the board will be permanently frustrated by monetary considerations. The opening of the remaining ward, which will give full effect to the plan of redistribution of beds amongst the main departments, the building, and more especially the maintenance, of the new infants' ward, and other minor but very important additions and improvements alike call loudly for more support to this great infirmary. The annual general meeting will be held towards the end of this month under the chairmanship of the new treasurer, Mr. T. L. Taylor, who has already won the confidence of the members of the board and staff, and who will prove a worthy successor to Mr. Charles Lupton, who happily still remains a member of the board.

PLYMOUTH PUBLIC HEALTH CONGRESS.

The Royal Institute of Public Health will hold its congress at Plymouth from May 31st to June 5th. The Section of State Medicine and Municipal Hygiene will be provided over by Dr. D. Llewelyn Williams, of the Welsh Board of Health, and a discussion will take place on tuberculosis, opened by Professor S. Lyle Cummins and continued by Dr. Nathau Raw and others. Another discussion will take place on the prevention of venereal disease, which will be opened by Dr. Mearns Fraser of Portsmouth and Mr. Kenneth M. Walker, and will be continued by Dr. Otto May, Mr. Wansley Bayly, and others. Dr. E. W. Hoop of Liverpool will read a paper on "The unification of local health administration," and Sir Thomas Oliver will speak on "Some medical and social problems of industrial hygiene." In the Naval, Military, and Air Section, of which Surgeon Rear Admiral Sir Daniel McNabb is president, papers will be read by Colonel A. B. Soltan, Lieut. Colonel T. S. Dudding, Surgeon Commander Digby Bell, Surgeon Commander D. H. C. Giron, and others; one afternoon will be devoted to a visit to the Royal William Victualling Yard, Plymouth. Professor J. Martin Beattie is president of the Section of Bacteriology and Biochemistry, in which a number of discussions will take place on streptococci and their infections, on syphilis, and on toxic jaundice; Dr. Hideo Noguchi will read a paper on his researches in yellow fever; Dr. W. G. Savago another on botulism and canned fruit; and other papers will be read by Professor Walker Hall of Bristol and Professor W. G. Wilson of Belfast. Lady Astor is president of the Section of Women and Public Health, in which Dr. J. W. Ballantyne will speak on "Now responsibilities of the maternity hospital," Professor Louis McIlroy on "The care of the expectant mother," and Miss Frances Ivens on "The organization and the care of maternity." The other subjects dealt with in this section will include infant welfare work, crippled children, and the racial and industrial aspects of maternity. The Harben Lectures will be delivered on June 1st, 2nd, and 5th, by Professor T. Madson of Copenhagen. The meetings of the congress will be held in the Municipal Buildings, and general meetings, receptions, etc., will be held at the Guildhall.

MEDICAL INSPECTION OF SECONDARY SCHOOL PUPILS AND
INTERVENING TEACHERS.

The London County Council has decided, for an experimental period of one year, to reduce the number of occasions on which medical inspection is necessary in the case of secondary school pupils. At present pupils attending secondary schools are inspected on admission, again at 12 years of age (if they were not older than that when admitted), and each subsequent year during attendance. It is now proposed to examine as a rule only at the ages of 12 and 15 years; examination at other ages will be made only in cases in which the health of the pupil appears to call for it. Candidates for the teaching profession are medically examined on five occasions—namely, when they become candidates for a probationer bursary, for a bursary, or for a student teachership, and when they enter and leave the training college. They will now be examined only three times—namely, on entering the secondary school, on entering the training college, and on leaving the training college. There may, however, be further examinations if the previous examination showed the desirability of keeping the case under review, or if the parent or headmaster has doubts about the candidate's health.

Scotland.

GLASGOW ROYAL INFIRMARY CLUB.

The twenty-fifth annual dinner of this club was held in the North British Station Hotel on the statutory date, the second Friday of March. The President, Professor W. K. Hunter, was prevented through family bereavement from being present, and in his stead Dr. J. B. Macdonald Anderson occupied the chair. The company numbered sixty-five, including a number of ladies. At the business meeting preceding the dinner the secretaries, Drs. W. A. Sewell and O. H. Mayor read the minutes, and presented the financial statement showing a credit balance. Mr. Henry Rutherford was elected president for next year, and the secretaries and committee were reappointed. The toast of the "Royal Infirmary" was given by the chairman, who recalled his own former chiefs, and compared the almost homely conditions

under which he watched Lister work in King's College, London, with the elaborate aseptic ritual he found established by Macewen in Glasgow in 1890. In his able reply, Dr. Freeland Forgue drew largely upon the ancient lore of the Infirmary from 1791 to 1832, the period covered by the history written by Moses Buchanan. Dr. Forgue thought the time was ripe for a complete history to be written up to the present day. Such a record would be a history of one of the greatest institutions of its kind in the world, as in it modern surgery under the presiding genius of Lister had its birth. The toast of "Past and Present Presidents" was proposed by Dr. G. Balfour Marshall, and replied to by Dr. J. Paton Boyd and Dr. Leishman in veins reminiscent and anecdotal. The enjoyment of an evening of camaraderie and reunion of old friends was artistically supplemented by song and story contributed by Drs. Wallace Anderson, George Dalziel, Wright Thomson, Charles Reid, Annabella Reid, James A. Adams, and Sewell. The box for contributions to the Medical Benevolent Fund was circulated as usual, and was found to contain £5 10s. 6d.

GLASGOW WESTERN INFIRMARY.

An interesting function in connexion with this institution took place last week in the Central Station Hotel, when a large and representative assembly gathered to do honour to Lord Glenarthur on the occasion of his retreat from the post of chairman of managers. Colonel J. A. Roxburgh, the new chairman, presided, and in the name of the managers presented to Lord Glenarthur a handsome piece of silver plate. In making the presentation the chairman reviewed the history of the institution from its inception in 1874, and paid tribute to the long and honourable record of service of his lordship over a period of thirty-four years, during seventeen of which he acted with great acceptance as chairman of the board. Sir Hector Cameron, on behalf of the staff past and present, expressed their high sense of privilege in being associated with the managers in honouring Lord Glenarthur. In acknowledgement, Lord Glenarthur thanked all his co-workers for the hearty co-operation all through his term of office, which had in large measure contributed to the success and development of the infirmary into the great institution and teaching centre which it was to-day. He referred to the important fact, in these days of enormous expenditure on maintenance, that their infirmary was still solvent. It was to the credit of Glasgow that, although the Government had agreed to give £500,000 for the assistance of voluntary hospitals whose expenditure exceeded their income from all sources, practically nothing would come to the three large infirmaries of the city. They still retained what the Scottish national poet called 'the glorious privilege of being independent,' upon which they set a far higher value than on any share of Government aid, if that were coupled with any control.

EDINBURGH SURGICAL APPLIANCE SOCIETY.

The annual meeting of the Surgical Appliance Society was held at Edinburgh, with Sir Montagu Cottrell, president, in the chair. The Honorary Superintendent, in submitting the report for 1921, said that during the year 291 appliances had been applied, 225 going to ex-servicemen in Craigleith and Tynecastle orthopaedic centres; the collaloid leg splints sent to the Sick Children's Hospital had also been found very beneficial. Mr. Henry Wade, who moved the adoption of the report, called attention to the display of work in the society's rooms. This type of surgical appliance was not peculiar to Edinburgh, but was an outcome of the war, differing from the commercial form. The splints were light, practical, and well made. He was glad to think that Miss Malcolm and her helpers were continuing their excellent work done during the war, keeping up the standard of excellence and carrying on in peace time the high ideals of service. There were many patients who required these appliances, but who could not afford to pay highly for them, and this work could not be put on a sound commercial basis, as the time required for making these appliances would make them too costly. It would be regrettable if the work had to stop for lack of funds, and he hoped it would be found possible to continue. He might mention that a dorsal splint in collaloid, which he had just seen made, enclosing the whole body, weighed two pounds, while a similar splint in plaster of Paris would weigh eighteen pounds. Professor Lorrain Smith seconded the adoption of the report, saying that there was often a difference of opinion about carrying on war charities, but such a society as this, which provided surgical comforts, was altogether good.

Correspondence.

A DIPLOMA IN TUBERCULOSIS.

SIR,—With reference to the letter of Sir Robert Philip in your issue of March 4th, p. 370, referring to the diploma of tuberculosis and describing the excellent courses arranged for the teaching of this disease at the University of Edinburgh, I am obliged to him for the friendly tone of his letter, and he will, I feel sure, pardon me if I differ from him as to the advisability of calling the new diploma by the name of Diploma in Public Health. The D.P.H. has become indissolubly associated in the minds of the general public with preventive medicine pure and simple. It is, I think, a very fine diploma, and the courses for it, if carefully pursued, form an excellent training for appointments such as those of medical officers of health, whose functions are as important as any in our common work of fighting disease. But the work of the medical officer of health is largely on administrative lines and involves an enormous variety of activities covering the whole field of hygiene. I am not one to belittle the importance of administrative medical work. On the contrary, I regard it as of the greatest possible value and as impossible to carry out efficiently unless based upon sound scientific knowledge.

But the Diploma in Tuberculous Diseases, which has been brought into existence in Wales, is not a diploma in hygiene. It is a diploma designed for those about to devote their lives to medical and surgical work in connexion with tuberculosis, and who are prepared to undergo advanced study of the fundamental problems underlying this disease. Why, then, should the issue be confused by calling it a Diploma of Public Health?

I have less to say in replying to the eloquent letter of Dr. A. Neville Cox. If the assumption is wrong that specialization in this disease is necessary—and this assumption underlies the appointments of tuberculosis physicians—then the granting of a special diploma is wrong also. In my opinion both are right, and it is this belief which has led me to advocate a Tuberculous Diseases Diploma.

No one who has served in the tropics can fail to have noticed the great improvement in the standard of medical work since the creation of the Cambridge, Liverpool, and London Diplomas in Tropical Medicine.

We have at our doors a disease which still very largely defies our methods of treatment and prevention, and which invites closer and more intelligent study. I am not without hope that the new diploma may bear good fruit in the future.—I am, etc.,

S. LYLE CUMMINS,

Professor of Tuberculosis, University College of
South Wales and Monmouthshire;

Cardiff, March 15th.

THE RECOGNITION OF AORTIC INCOMPETENCE.

SIR,—I have read with great interest the paper in your issue of February 4th by Dr. E. M. Brockbank on the recognition of aortic incompetence. While quite agreeing with the writer on the frequency with which a diastolic murmur is heard down the left side of the sternum without the usual signs of aortic regurgitation, such as a water-hammer pulse, a large pulse pressure, a capillary pulse, etc., being present, I am not so sure about his interpretation of the origin of this murmur. Some years ago I gave a paper before the Association of American Physicians¹ under the heading of "Passing leakage of the pulmonary valve," in which a number of just such cases as Dr. Brockbank describes were recorded, where a soft diastolic murmur was present down the left border of the sternum without any signs of aortic disease, and which I thought were probably of pulmonary rather than of aortic origin. A feature of these cases was that the murmur tended to come and go, being present now and again absent. I note that in several of Dr. Brockbank's patients this variability occurred. He assumes that the bruit must have been missed at medical boards. This is quite possible, and far be it from me to insist upon the infallibility of such boards; but in some of my cases the same observer found the murmur there on one occasion and absent on another, which suggests that it was the bruit and not the examiner that varied.

My hypothesis was, and is, that in certain weakened states the pulmonary muscular ring is occasionally so relaxed

that it fails to support the fibrous ring of the orifice, and thus permits of leakage there. If the pressure in the pulmonary artery happen to be high, as is most apt to be the case in mitral stenosis, such leakage often occurs, as was pointed out by Graham Steel.

In some experiments done in 1911 I found that in a bullock's heart a water pressure of 6½ ft. was sufficient not only to cause the pulmonary artery to balloon out in a remarkable way but also to so stretch the pulmonary orifice as to cause leakage. If, while a much higher pressure than this was being applied, one supported the pulmonary orifice with the fingers, no leakage occurred. The same experiment repeated upon a number of human hearts showed that a water pressure of 11 to 18 inches was sufficient to cause leakage at the pulmonary orifice. Such a pressure is much less than what occurs during life, but in our experiments the tissues were dead, and hence more easily stretched. If a previously adjusted ligature prevented the distension of the opening, the pressure could be greatly raised without causing leakage.

Dr. Hugh Stewart in 1909 demonstrated before the Association of American Physicians the importance of the muscular ring below the aortic orifice in preserving the integrity of that orifice, and in the same way Dr. Arthur Keith and the late G. A. Gibson² showed that a loss of tone in the muscular fibres surrounding the mouth of the pulmonary vessel allowed of stretching of the fibrous tissues there. The normal pressure in the normal pulmonary artery will not, of course, cause leakage, because the tone of the muscle below the orifice is good; but if the artery be relaxed from any cause (and the muscular support of the orifice may share in the relaxation), or if the pressure in the artery be raised, then leakage is apt to occur, and will be evidenced by a diastolic murmur down the left border of the sternum and in the tricuspid area. If this leakage be considerable, the right ventricle will dilate, and such dilatation will, amongst other things, tend to shift the cardiac apex towards the left. True hypertrophy of the left ventricle not only causes the apex to shift to the left but also downwards, which did not seem to be the case in any of Dr. Brockbank's patients.

Thus, while agreeing that a diastolic murmur heard down the left border of the sternum is in very many cases due to aortic leakage, I think we must conclude that such a murmur is not necessarily of this origin in the absence of all the classical signs of aortic regurgitation except the murmur, but rather remember that an increased pulmonary pressure or a relaxed pulmonary artery (and especially both these factors combined) may be sufficient to cause leakage of the pulmonary valve, which will produce just such a murmur as Dr. Brockbank describes.

When such a murmur tends to be present at one examination and absent at another the likelihood of its pulmonary origin becomes greater.

In supporting the hypothesis that this diastolic murmur is often of pulmonary orifice origin I say nothing original, but am merely echoing the views of R. B. Preble, W. S. Thayer, the late G. A. Gibson, and many others.—I am, etc.,

Toronto, Feb. 23rd.

R. D. RUDOLF.

PROSTATIC ENLARGEMENT.

SIR,—Perhaps you will be good enough to allow me space in which to reply to the two letters published in the *BRITISH MEDICAL JOURNAL* of March 11th referring to my Hunterian lecture on prostatic enlargement.

In the first place I would like to thank Mr. F. T. Paul for calling my attention to his extremely interesting article published in the *Lancet* of July 30th, 1910. In this paper Mr. Paul refers to the parallel existing between enlargement of the prostate and the changes in the female breast that occur at the climacteric. The article contains ten illustrations of sections of the prostate and of the breast, and the similarity of the histological changes in the two organs is beautifully demonstrated.

I regret that Mr. Paul's paper had escaped my notice until reading his letter. However, the fact that working along independent but converging lines of thought we have both arrived at conclusions on the subject of prostatic enlargement that are so similar surely adds strength to our observations. The parallel existing between the prostate and the breast has been noted by several observers, and it is rather remarkable that so little emphasis has been laid on the possibility of prostatic enlargement having a similar pathology to that of involutionary changes in the breast.

² Arterial pressure, *Edin. Med. Journ.*, March, 1911.

In reply to Dr. A. F. Martin's letter, so far from "giving the lie direct to the position in which he finds himself," my observations on the prostate are such as to encourage efforts to deal with minor degrees of enlargement by means of organotherapy. I am interested to hear that he has had success in treating certain cases by means of prostatic extract. Although I have not used this preparation in a sufficient number of cases to justify any general statement, I can certainly recall several cases of minor degrees of enlargement in which the exhibition of prostatic extract appeared to afford relief. At the present moment I am collecting all available evidence on that subject, and shall be grateful to Dr. Martin and to any other practitioners who have used the preparation if they would furnish me with particulars of their experience.—I am, etc.,
London, W., March 11th.

KENNETH WALKER.

HOLLOW VISCERA AND VESSELS: CURVATURE AND PRESSURE.

SIR,—I have been much interested in the paper on the relation of curvature to pressure in hollow viscera, published in the *British Medical Journal* of February 18th by Dr. Cranston Walker; as I also was, many years ago, when Sir Robert H. Woods sent me a copy of his communication to the *Journal of Anatomy and Physiology*, vol. xxvi, on the same subject.

I think, however, for practical purposes that the explanation I gave in your issue of February 5th, 1921, is likely to be more useful, as it shows more graphically the mechanical advantage which the heart and other hollow viscera may have when their chambers are small compared with when they are large.

My purpose, however, in now writing is to call attention to some of the physiological consequences, in the case of the heart, of the physical principles which Sir Robert H. Woods, Dr. Cranston Walker, and I have endeavoured to elucidate, of which perhaps the most striking is the greatly enhanced importance of the auricle.

The auricle begins its contraction before the ventricle, and becomes small as the ventricle becomes large and full. If their contractions should overlap, the auricle not having finished its contraction when the ventricle begins to contract, the auricle by its small size at the time might easily be more than a match for the large full ventricle. Suppose the auricle to be empty and contracting hard, a thick muscular mass would then be guarding the auriculo-ventricular orifice, and regurgitation could not take place even though the valves had not fully closed when the ventricle began its systole. That the auriculo-ventricular valves have not normally fully closed till nearly the moment of the opening of the aortic valves was always maintained by Professor Potain, probably the greatest French cardiologist of the last century. The apex beat (*choc du cœur*) Potain found fully developed before the occurrence of the sound indicating the valve closure.

Professors Roy and Adami, in their classical paper published in the *Practitioner*, vol. xlv, gave on page 251 a series of graphic curves showing the relation in time of the principal cardiac events. They show that the papillary muscles commence to contract only when the aortic valves open. They also show that the auricular contraction is normally maintained till the aortic valves open.

One is compelled, on reflection, to suppose that the auricle guards the auriculo-ventricular orifice during the first phase of the ventricular contraction, and its ability to do so is a consequence of the physical advantage it has over the ventricle, due to their relative sizes at the time.

In cases of severe mitral stenosis the overlap of the contraction of the hypertrophied auricle on to the contraction of the ventricle is almost certainly increased. It takes more time for the auricle to empty its contents through the narrowed mitral orifice, and the so-called presystolic murmur goes into ventricular systolic time in harmony with the prolonged auricular contraction. Often the mitral valve, as indicated by the antopsy, must have been incompetent for years, yet the history of the case shows that there was no regurgitation or systolic murmur till late in the illness, when, on account of auricular dilatation, the auricle could no longer guard the orifice and prevent regurgitation.

Such possibilities for the auricle as I have indicated are the normal consequences of the physical principles which Sir Robert Woods and I in the past, and Dr. Cranston Walker lately, have endeavoured to explain.

In my paper "Cardiac peristalsis and mitral stenosis" in the *British Medical Journal* of April 2nd, 1921, I have entered more fully into this subject.—I am, etc.,
Menton, France, March 8th.

D. W. SAINWAYS.

SIR,—I feel sure Dr. E. E. Laslett is right, and that variation in effort due to varying lengths of the contracting muscle would enter, to some extent, into the equation; but its influence would, I should think, be small, and perhaps negligible, in comparison with that of the diminished radius of curvature.—I am, etc.,
Dublin, March 13th.

ROBERT H. WOODS.

HAEMATOPORPHYRINURIA.

SIR,—In the account, published in the *British Medical Journal* of this date, of an address given by me to the Oxford Medical Society, the reporter has omitted to state that the case of congenital porphyria to which I referred was shown at the meeting of the Association of Physicians in Birmingham by Dr. Leonard Mackey, by whose kindness I was enabled to show a specimen of the urine. I hope that Dr. Mackey will, before long, publish a full account of his case. May I also correct two errors in the report—namely, there are cases of porphyria which are not congenital and not due to sulphonal drugs, and even among the congenital cases there are some without hydroa.—I am, etc.,
Oxford, March 11th.

ARCHIBALD E. GARRON.

ASTHMA AND THE MENOPAUSE.

SIR,—The explanation given by Dr. Kark in your last issue (p. 416) as to how the case of asthma (quoted by Dr. MacBee Ross) which occurred subsequently to an artificial menopause was cured by ovarian extract is very interesting. But I am afraid that it will not hold water when a large series of cases is considered.

The interactions of the hormones of the various endocrine glands is a most difficult question, and especially so in asthma. I do not think we can compare, as Dr. Kark does, the conditions existing, as far as hormones go, in a woman who has had an artificial menopause with those in pregnant women. I agree that a hyperpituitarism occurring in both is the cause of asthma. One would rather imagine that there was a shortage of pituitin in pregnancy, if we note its common favour in the midwifery bag.

But even if we allow that there is a deficiency of the ovarian hormone in pregnancy and after an artificial menopause, and that this leads to hyperpituitarism, and this to asthma, the whole basis of the argument falls to the ground in my experience that whereas asthma commencing *de novo* in pregnancy is extremely rare, the exact opposite is quite common. Numbers of one's patients will state that the only free time they have had from asthma for years has been during the times when they have been pregnant. With one patient recently this had occurred regularly during six pregnancies; she, by the way, had a nose that was full of as regards their asthma or other anaphylactic symptoms just before their periods I have not noticed any difference one way or the other, for better or worse, to occur at the menopause.—I am, etc.,
London, W., March 12th.

FRANK COKE.

PROTECTIVE INOCULATION AGAINST TYPHUS.

SIR,—In the *British Medical Journal* of August 13th, 1921, the experimental work done in this direction in Japan on monkeys was quoted from the *Japan Medical World*. Employing small quantities of the diluted blood of typhus patients, immunity was produced in monkeys without any preceding febrile reaction. No information upon the inoculation in men was given.

The following observation of a colleague (Dr. Mazzefer Bey) of the inoculation practised among the medical men in Baghdad during an epidemic of typhus in 1916, before the British occupation, may be interesting to others:

The blood of a case of typhus in fresh development was withdrawn, defibrinated, sterilized, and 5 c.cm. of the serum injected hypodermically at one time. Many of the doctors of the military medical service in Baghdad were inoculated, and no case of typhus occurred among those inoculated, and was no pain and no other reaction from the injection. I should be glad to know of other experiences in this direction.—I am, etc.,
Baghdad, Feb. 10th.

T. B. HEGGS,
Medical Officer of Health.

HAEMORRHAGE IN TONSIL OPERATIONS.

SIR,—Recently there has been much correspondence in the JOURNAL concerning haemorrhage following operations upon the tonsils. To me it seems there has been too much unnecessary explanation as to the occurrence and as to the counteracting of this fault in operative technique. So far in the correspondence not a writer has, I consider, really hit the point, and I am therefore drawn into the discussion much against my wish, for I would have preferred a throat surgeon of more repute to have detailed experiences similar to mine.

I think that we must acknowledge that we owe a good deal to the American throat surgeons for improvements in operations on the tonsils. I have been following their procedures for some four years and more, and I am forced to the belief that general anaesthesia is, except in rare instances, unjustifiable in the performance of the operation of enucleation of the tonsil in the adult. This operation can be very satisfactorily performed under local anaesthesia, and it is without question in my opinion the method of choice. When considering the advisability of enucleating tonsils it is essential to inquire into the question of the coagulability of the blood. In any patient whose history suggests, even in the slightest degree, the occurrence of "bleeding," I make it a rule to do a blood time-test. Should this not be satisfactory the blood is improved in its coagulability. I find that haemostatic serum of Parke Davis is superior to any other method, and I have never yet failed to bring the patient's blood to a satisfactory state with this drug.

In all cases of tonsil operations I give, as a routine in both private and public hospital cases, 2 c.cm. of the serum three hours before the operation and a hypodermic injection of morphine q.s. at the commencement of the operation. I always perform these operations in a hospital. The essential point to aim at in injecting the solution is to bring about "block" anaesthesia. After swabbing the fauces and soft palate with 10 per cent. solution of cocaine, the needle is inserted into the anterior pillar of the fauces about 5 mm. from its border at the junction of the upper and lower two-thirds. The needle is directed upwards, outwards, and backwards for an inch and 1 to 1½ c.cm. of a 1 per cent. of cocaine or 2 per cent. novocain is injected, the tonsil being avoided by the needle as it is advanced. An injection of a few minims is made in the region of the lingual nerve about the level of the base of the tongue. A similar small injection I make into the palate immediately above the tonsil. Previously, when I used the infiltration method of anaesthetizing the tonsil region, I had frequent cases of bleeding. With this latter method of "block" anaesthesia I have had no troublesome cases whatsoever. In public hospitals I use a sharp guillotine and perform the operation by a quick method, following the procedure of Sluder. There is usually an immediate sharp haemorrhage, but this ceases in a short time. In my private work I either do the quick method or more often a slower method, using a blunt guillotine and crushing the tonsil out much after the method of La Foree, and in rare cases by dissection, using a blunt guillotine as a fixation forceps and dissecting with a blunt Dan McKenzie dissector. I am convinced that there is really no necessity for any elaborate procedures in performing these operations. I have myself only once had to sew up the pillars of the fauces, and this was when I had used general anaesthesia. I have come to the conclusion that the more damage done to the tonsillar bed the more likelihood of post-operative haemorrhage. It is only reasonable to believe that, with a patient under ether anaesthesia, the bleeding may be severe. Under local anaesthesia, by the slow crushing method one can almost always enucleate the tonsils with as little loss of blood as one teaspoonful for both tonsils.

I do not wish to imply that I am using any methods other than those which are already practised by many throat surgeons.—I am, etc.,

R. GRAHAM BROWN,
Honorary Surgeon-in-Charge, Ear, Nose, and Throat
Department, General Hospital, Brisbane,
Queensland.

December 28th, 1921.

X-RAY DEPARTMENTS.

SIR,—In the BRITISH MEDICAL JOURNAL on February 18th appeared a very interesting letter from Dr. C. H. Ross Carmichael on x-ray departments, interesting as containing an important suggestion, but still more interesting as indicating the growing spirit of dissatisfaction with the general practitioner's opportunities of diagnosis and treatment. This dissatisfaction is, I think, to be welcomed, for there can be

little doubt that at the present time, for the general practitioner dealing with middle-class patients of small means, these opportunities are far too restricted.

However, if those who think like Dr. Carmichael will unite in pressing their views that there should be public x-ray departments, I do not think they need wait long for the realization of their plans; but "public" need not necessarily mean State or municipal, nor should treatment be gratis. It is also very important that nothing should be done to interfere adversely with the interests of those already engaged in x-ray work. Such a public x-ray department should and, I believe, can be run on entirely business lines, although assistance from some generous philanthropists may be necessary at first.

The Kensington Division, British Red Cross Society, as already announced, has started a clinic for physio-therapeutic treatment at 14, Prince of Wales Terrace, Kensington, in the running of which attention is given to these considerations. Whether the B.R.C.S. will ever be prepared to establish in co-operation with the medical profession such public x-ray departments I have no knowledge; but, if not the B.R.C.S., some other body of public-spirited citizens may be persuaded to take up the work.—I am, etc.,

London, W., March 9th.

HAROLD H. SANGUINETTI.

SUN OR AIR?

SIR,—A question of great interest has been opened up by Dr. Leonard Hill by his research on "Metabolism of children undergoing open-air treatment, heliotherapy," etc. (February 25th, p. 301).

He shows that he—the laboratory worker—is clearly at variance with Sir Henry Gauvain, the clinician. Professor Hill attributes most of the beneficial effect of the treatment carried out at Lord Mayor Treloar's Homes at Alton and Hayling to the effect of the cooling power of the open air in the exposed body of the child under treatment. Sir Henry Gauvain attributes the benefit mainly to heliotherapy. Each of course recognizes the importance of other factors.

Which is the more potent agent in treatment is important from the practical point of view. The figures in Dr. Hill's article are all in favour of open air *per se* being the more active agent, and in a climate like ours it is well for us it is so. A decision on the relative merits of heliotherapy and open air *per se* in improving general "tone" may possibly be reached by an investigation which is immediately to be undertaken by the Medical Research Council. The workers are to investigate the biological action of light, and doubtless data will be obtained from clinicians, for the subject is too complex for us to rely on laboratory findings alone.

In the meantime we must go to work with the knowledge at our disposal at present, and it is this—the cooling power of the open air stimulates metabolism and cures disease. It doesn't matter a great deal whether the sun is shining or not.

The profession owes much to Dr. Hill for giving us a scientific explanation of the manifest advantage of the open-air treatment of cases of surgical tuberculosis, and it is a line of treatment which is often the only one at our disposal in those prolonged cases of suppuration we all have to care for.—I am, etc.,

Biron, Feb. 28th.

A. C. DEVEREUX.

REPEATED TREPHININGS.

SIR,—Referring to Sir Charles Ballance's request for further particulars with regard to Philip of Nassau, I think he may be interested in the following details. Solingen says (*Manuale Operation der Chirurgie*) that Philip of Nassau, Lord of Grinhuysen, was the son of Justinus de Nassau, and grandson of William I of Orange. He was trepanned twenty-seven times, and the surgeon who operated on him was Mr. Hendrick Chadborn of Nymegen. The patient gave a certificate, dated August, 1664, saying that he was well on that date, and this certificate was given to Solingen by Amos Chadborn, a schoolmaster, and brother of the surgeon. Solingen died in 1687, so that he may have met Philip of Nassau, although he does not say so, and the name is not again mentioned.

The story seems to be authentic. The injury was a comminuted fracture of the skull, and probably required the removal of pieces of bone on many occasions, but it is unlikely that the use of the trephine was always necessary. Apart from his surgical experiences this Philip of Nassau does not seem to have had any special claim to fame, and I do not find his name recorded elsewhere. He must, how-

ever, not be confused with Philip of Nassau, who died in 1595, and who was the son of John of Nassau-Dillenburg, and nephew of William the Silent. He was cousin to the Justins above mentioned, and cousin once removed to Solingen's Philip. He was a brilliant cavalry leader under the command of his cousin Maurice of Orange, and was killed in a skirmish with the Spaniards.—I am, etc.,

London, N.W. March 5th.

H. A. CLOWES.

CLINICAL ASPECTS OF ABDOMINAL TUBERCULOSIS.

SIR,—The interesting and excellent lecture by Mr. John Morley (p. 383) opens up a wide field for discussion. The questions arising out of this lecture are, first, can we diagnose a bacterial condition clinically? secondly, are we justified in naming a condition without a thorough bacteriological examination? My answer to both these questions would be in the negative.

It is so much easier to "repeat the tales of ye-terday" than it is to work out new ones for ourselves that we are prone to go taking what we have been taught or read as "gospel."

I have so often proved my own clinical diagnosis wrong that I am now very slow to put a name to a condition without a full investigation. The correctness of a diagnosis depends upon its completeness, and a complete diagnosis cannot be made without using all the means at our disposal.

This letter is the result of the stimuli received from reading Mr. Morley's lecture, and is in no way a criticism.—I am, etc.,
Belfast, March 11th.

J. S. RENTON, M.B.

MEDICINE IN ASSAM.

SIR,—Dr. W. A. Murray, writing on the above subject in the JOURNAL of January 28th (p. 165), commences his letter by admitting that he "was never a tea-garden doctor." The value of his opinions may therefore be safely left to your readers. The statements made by me regarding the conditions of tea-garden practice in Assam are founded on actual personal experience—not on hearsay—and are fully corroborated by the letter of "Experienced" in the same issue of the JOURNAL in which Dr. Murray's letter appears.—I am, etc.,
Bombay, Feb. 25th.

W. G. FORDE.

PREVENTION OF VENEREAL DISEASE.

SIR,—Is it not full time that the talented scribes who contribute so largely to your correspondence columns should cease quibbling over calomel cream and Condy's fluid, which have led to Babylonian confusion? What really matters—namely, the wiping out of venereal disease—has been practically lost sight of in the whirlpool of statistics which have been advanced in support of and in opposition to preventive measures. Such contradictory statistical evidence is not worthy of a moment's consideration, and should be abandoned once and for all, and replaced by united action in endeavouring to find ways and means to check the spread of a disease which is undermining the constitutions of our most vigorous youths. The question is of national importance, and its proper handling concerns chiefly the medical profession, who should investigate the subject without puritanical bias or interference from outsiders having neither knowledge nor experience of the disease. The responsibility of bringing about a healthier state of affairs rests entirely with the profession, that deals with the material side of man and his functions, and whose duty it is to publish broadcast the best-known methods of preventing disease. Although not certain in their action, they might lessen its prevalence. There is no time to spare for the tardy and probably futile operation of moral persuasion: the passion of man is too strong to be controlled even by the knowledge of the dire effects of venereal disease. The attempt to establish continence by moralizing is but a poor reed to rely on, and will in future have no better results than those produced by the admirable lessons of temperance and chastity contained in Proverbs, Deuteronomy, Leviticus, Solomon, and St. Paul, which prove that the purifying influence of Christianity has failed after a lengthy trial. It therefore behoves the profession (although with regret) to seek a more expeditious method of saving our youths, without in any way detracting from the possible good which might accrue from the well-considered advice of those whose duty it is to watch over our spiritual lives. We cannot lose sight of the fact that the natural passions of man are as difficult to change as it is to change the Ethiopian's skin or the

leopard's spots. The wise course, then, is to neutralize as far as possible the evils which are caused by the consumption of such passions by the best-known methods of prevention. There is no reason why we should pin our faith to calomel cream and Condy's fluid, neither is there to warrant their disuse, whilst seeking something better, which should be in the nature of a prophylactic applicable to both sexes. So far, the nearest approach to general utility is the sheath, which, if properly made of good material, affords a safeguard to the parties. The subject of "the prevention of venereal disease" is not a savorious one, but its importance is sufficient justification for plain speaking.—I am, etc.,

T. D. HARRIES, F.R.C.S. Eng., M.R.C.P. Lond.

Aberystwyth, Feb. 23th.

*** We are compelled to hold over a long letter on this subject, received this week from Mr. E. B. Turner and Mr. Charles Gibbs.

MUCOCELE OF THE FRONTAL SINUS.

SIR,—Mr. J. Acomb's case of mucocele of the frontal sinus (March 4th, p. 344) is of considerable interest, but if I might differ with the author on two small points, I would submit—

1. That such conditions are not so rarely due to previous trauma as he seems to suggest; in fact, by some of the leading authorities, this is held to be one of the commonest causes. If the fronto-ethmoidal region be examined in a number of cases, either in the dry cut specimen or at operation, there is frequently found what may be described as an abnormal encroachment of the anterior ethmoidal cells upon the fronto-nasal duct and the floor of the frontal sinus. It is in these cases that an injury, perhaps forgotten, and possibly much less severe than that described by Mr. Acomb, may produce a definite obstruction to normal drainage, and so give rise to the morbid condition under consideration.

2. With regard to the precautions adopted for securing drainage. In my experience this is the most important part of the operation, from the point of view of ultimate results, and cannot be too thoroughly undertaken. I have found that it needs considerably more than a gauze drain (however large) left for twenty-four hours to establish permanent drainage in the newly formed duct, which is only too apt to close up with granulations and scar tissue. I now make a practice of inserting as large a piece of thick rubber tubing as is possible, and leave this *in situ* for ten days; even after this has been done I find the periodical passage of sounds is necessary until the drain has become "consolidated" and permanently efficient. Without these careful, if tedious, measures I should greatly fear a recurrence sooner or later.—I am, etc.,
Worcester, March 6th.

J. B. CAVENAGH.

GERMAN-MADE X-RAY APPARATUS.

SIR,—The letter signed "A Manufacturer of British Apparatus" in your issue of February 25th (p. 331) raises a question of very great importance at the present time. The apparently casual manner in which certain people and institutions place their orders for electro-medical apparatus—often of a substantial nature—with German firms is disconcerting, when it is considered that English manufacturers are able to compete in price, quality, and time of delivery.

When the war broke out, manufacturers in this country were begged to produce certain indispensable electro-medical apparatus, which, owing to the previous attitude of the home consumer, had been imported from abroad. As might have been expected, the necessary apparatus was produced, and before long in such quantities that the medical services were never at a loss for a single article of this nature. Not a penny of subsidy in any shape or form was paid to these manufacturers, nor was the financial result of the war demand sufficient to place any of these firms in a favourable position to meet post-war depression. It is therefore much to be regretted that these same manufacturers do not now receive from British consumers that support to which the quality of their products would appear to entitle them.—I am, etc.,
London, March 6th.

ANOTHER BRITISH MANUFACTURER.

PROFESSOR MOURE, the well-known oto-laryngologist of Bordeaux, has been made a Commander of the Legion of Honour.

A GOLD medal has been presented to Professor Arnold Netter on the occasion of his retirement from hospital service in Paris. He was *chef de service* at the Hôpital Trousseau for twenty-five years.

Obituary.

AUGUSTUS D. WALLER, M.D., LL.D., F.R.S.,

Director of the Physiological Laboratory of the University of London.

On March 11th Professor Augustus D. Waller died from cerebral haemorrhage after twelve days' illness. He was born on July 12th, 1856, the only child of Dr. Augustus Volney Waller, F.R.S., whose name, in adjectival form, has become part of the terminology of physiology through his observation that nerves when separated from their cells of origin undergo degeneration; he used the method for tracing the course of nerve fibres especially in connexion with the spinal nerve roots then recently investigated experimentally by Magendie. The writer of these lines, who knew the younger Waller for some forty years, only remembers to have seen him really aroused to anger on a few occasions, and then almost invariably it was because he considered his father's work was being misrepresented or depreciated. In a brief dedication to his father's memory of his *Introduction to Human Physiology* the son summarized the elder's work in the following words: "Emigration of . . . 1846; degeneration and regeneration of nerve, . . . 1846; region, 1851; vaso-constrictor action of sympathetic, 1853."

Augustus Désiré Waller was born in Paris, where at the time his father was engaged in physiological research, and received his early education at the Collège de Genève; the ease with which he spoke and wrote French had a considerable influence on his scientific career, and he usually communicated the result of his researches to French as well as to English societies. His father died in 1870, and his mother took the son to Aberdeen, where he graduated M.B., C.M. in 1878, and M.D. three years later. He studied in Edinburgh also, and soon after graduation went to University College, London, to work in the physiological laboratory under Burdon-Sanderson. In 1880, and again three years later, he received scientific grants from the British Medical Association, and in 1884 was appointed a research scholar. His first independent appointment was that of lecturer on physiology at the London School of Medicine for Women, where he met the lady who became his wife and life-long comrade and helper. Afterwards he was appointed lecturer on physiology in the medical school of St. Mary's Hospital, a post he retained until when about twenty years ago the physiological laboratory of the University of London was formed, mainly through his efforts.

Waller's name became known to physiologists chiefly through his investigations of the electric phenomena of the nervous system and of the heart. The rise of electrocardiology as a branch of medical science was largely due to his pioneer work. He at first used the mirror galvanometer, then the capillary electrometer, and finally the string galvanometer. In these researches, as in all he undertook, he showed remarkable originality in the devising of experiments and great ingenuity in the designing and construction of apparatus, which sometimes looked rough but were always efficient. He gave a general account of many years' work in the Oliver Sharpey lectures on the electrical action of the human heart delivered before the Royal College of Physicians of London in 1913. The other work in which he was particularly engaged in his earlier days was the investigation of the electric currents in living structures, especially in nerve and muscles, but also in the skin and retina, and in plants. He published numerous papers on these subjects, and in 1903 summarized the results in a book entitled *Signs of Life from their Electrical Aspect*. The high estimation in which his work was held was shown by the fact that he was elected F.R.S. in 1892 at the relatively early age of 35.

During his investigation of the electric currents of nerve and muscle he made observations on the effects of gases and anaesthetic vapours on the irritability of these tissues; it was in this way that he became interested in practical anaesthetics. In the Croonian lecture delivered before the Royal Society in 1896 he related his observations on isolated nerves, and in the following year, when President of the Section of Anatomy and Physiology of the Annual Meeting of the British Medical Association at Montreal, he opened a discussion on the relative efficacy of ether and chloroform; in this address he insisted on the paramount necessity for careful dosage in the administration of chloroform, a subject to which he recurred in a paper in our columns in 1898. In his view the risk depended mainly on the percentage of chloroform vapour in the air, and he contrived an apparatus

for controlling the proportion. He continued to occupy himself with the methods for the estimation of the quantity of chloroform in mixtures with air, and in the practical application of his own experimental observations and those of others. He was seriously disturbed by the number of deaths under chloroform, believing that the majority of them might be avoided, and on May 20th, 1901, addressed a letter to the Council of the British Medical Association urging that it should give consideration to the question of accidents during anaesthesia. It was not a new question for the Association, which had appointed a committee on chloroform in 1877, and another on anaesthetics generally in 1891. In 1901 the Council decided that the question should be attacked along a different line of approach—the experimental. The special chloroform committee appointed consisted of Dr. (now Sir James) Barr, Dr. Dudley N. Buxton, Sir Victor Horsley, and Professor Waller. The committee subsequently co-opted Mr. A. Vernon Harcourt, F.R.S., and Professor Dunstan. It was instructed to investigate methods of quantitatively determining the presence of chloroform in the air and in the living body, and to determine if possible what is the minimal dose of chloroform which will secure an adequate anaesthesia for operations and at the same time not endanger life. Professor Waller at first acted as chairman of the committee, but retired before the report of the committee was published in 1911. The volume, which was edited by Dr. Buxton, contained among the appendices to the report two papers by Professor Waller, both dealing with the quantitative estimation of chloroform; they had been published in our columns in 1902.

During the last years of his life Waller was particularly interested in two subjects—the cost of muscular work as measured by the amount of carbon dioxide exhaled, and the emotive response of man to pain or the threat of pain. Both afforded evidence that Waller's originality of mind and ingenuity in contriving experiments were in no degree diminished, and illustrated his curious power, due to the fascination of his personality, of inducing men voluntarily to submit to experiments not wholly agreeable. Some of those on the cost of muscular work were carried out in the physiological laboratory of the university on ex-soldiers he engaged to do measured work, others in London printing offices, among his willing subjects being members of the printing staff in the composing room of the BRITISH MEDICAL JOURNAL. His results were communicated to various societies and many of them were published in a series of papers published in our pages during 1920 and 1921. The other inquiry was carried out on friends he inveigled into his laboratory at the university, or into the private laboratory he had fitted up in his roomy old house in Grove End Road, St. John's Wood. It was certainly a weird experience to find that one reacted more strongly to the threat of a match than to the actual burn. The observations contain a lesson for surgeons—that the fear or apprehension of pain may be worse than its realization.

Waller's contributions to medical and physiological science were very numerous; a large part of them is to be found in our volumes, in the *Transactions of the Royal Society*, and in the *Journal of Physiology*. His *Introduction to Human Physiology*, to which reference has already been made, reached its third edition in 1896, and in the same year he published *Animal Electricity*. His academic distinctions, honorary memberships, and degrees were many. In 1889 he became a Lauréat of the Institute of France for his discovery of the electromotive action of the human heart, and its record by electrocardiogram, and in 1892 the Royal Academy of Science of the Institute of Bologna awarded him the Aldini prize. He was a corresponding member of many foreign learned societies and academies, and an honorary member of the Council of the University of Tomsk.

Professor Waller married Alice Mary, daughter of the late Mr. George Palmer, M.P. for Reading, and had three sons and a daughter. The house in St. John's Wood, scarcely less than his laboratory at South Kensington, was a centre of inspiring work and fertile ideas, for his wife shared in all his labours; her recent illness no doubt precipitated the stroke from which he died. The Physiological Laboratory of the University of London was established in an upper floor of the Imperial Institute building, and Waller was its unpaid director. It was equipped by gifts made by himself and some of his friends. The research and teaching carried out there had great influence upon physiological progress; but a year ago there was an unfortunate proposal to close the laboratory, on grounds of economy. Happily, wiser counsels prevailed,

and the Senate resolved to continue the laboratory until the end of 1923, and to increase its grant for upkeep.

He took up motoring in the early days, and was never without one or two cars, not always of the newest patterns, but eable in his experienced hands of serving his daily needs, and of doing long journeys in which he and his inseparable companion and aid Mrs. Waller found much pleasure. When he went to Paris, as he did pretty frequently, either to attend meetings or to work at the Mace Institute, of which he was free, he shipped his car from Southampton to Harre and drove the remainder of the journey. Recently when he was investigating the physiological cost of muscular work measured by the exhalation of carbon dioxide he and his assistant, Miss de Decker, a Belgian lady, obtained leave to make observations on Belgian soldiers during route marches at various paces. Here again his car came in handily. Few men got more work and more fun out of a motor car. He loved fun as much as work, and entered into both with the same zest. But he was a physiologist first and last; he thought it and talked it. He was a good talker, eager, emphatic, sometimes a little brusque and impatient with slower-witted folk. But if some flying dart wounded he was quick to make amends, a little puzzled sometimes to understand why anyone should mind a prick which he took himself as part of the fun of the game—a generous and loyal friend.

Sir THOMAS LEWIS, M.D., F.R.S., writes: May I add a few words of tribute to the memory of Professor Waller, whose death will be much regretted by both physiologists and physicians in this country and in many other lands. He was a man of unusually keen intellect, and has been for very many years a notable figure in British physiology. His brilliant powers of exposition will long render his demonstrations at the Physiological Society memorable. His early work on electro-physiology, extensive and thorough as it was, and his observations upon chloroform, are well known. Waller was the first to show that currents set up by the beating of the human heart can be recorded; he was the first to obtain a human electro-cardiogram. Considering his work in the light of its development, this has been perhaps the main, though by no means his sole, contribution to the science of experimental medicine. The discovery long preceded the introduction of the string galvanometer, and was the more remarkable in that it was accomplished in the eighties. It will remain a milestone in the history of this branch of knowledge. Although those who explored the same field could not always see eye to eye with Waller in his later views, nevertheless they fully recognized that in this field he was a pioneer, and that his early observations went far to prompt further developments along similar lines.

HENRY KINGSMILL ABBOTT, M.D.,

Medical Superintendent, Hants County Asylum.

WE regret to record the death of Dr. Henry Kingsmill Abbott, Medical Superintendent of Hants County Asylum, Fareham, February 27th, 1922. Dr. Abbott was born at Monkstown, Dublin, in September, 1863, and was the eldest son of the late Rev. Thomas Kingsmill Abbott, Litt.D., D.D., Junior Fellow of Trinity College, Dublin. He entered Trinity College in 1881, and having obtained term honours in natural science and logic, he graduated B.A. in 1885. He obtained degrees of M.B., B.Ch. in 1887, and of M.D. in 1889. He took the D.P.H., Conjoint Board, Ireland, with honours in 1898. His professional career was almost entirely devoted to asylum work. He obtained the position of Junior Assistant Medical Officer to the Hants County Asylum in 1890, and in 1896 he was appointed Medical Superintendent. Dr. Abbott was for some time Stewart Lecturer in Mental Diseases at Trinity College, Dublin, and also Examiner in Psychiatry at the university. He was a man of wide culture, but unobtrusively retiring in disposition. He was extremely conscientious, and administered his asylum with conspicuous ability and unspurious fairness. He bore his last illness with extreme fortitude, he scarcely ever referred to the subject even to his most intimate friends, and he carried out his work until shortly before his death. He was buried in the asylum cemetery, as he had wished, and the funeral service was attended by his brother, the Rev. Canon Abbott, B.D., and her relatives, members of the visiting committee, the staff, and a large gathering of his personal friends. His loss will be severely felt in the institution, which he had served faithfully for thirty-two years.

THE LATE PROFESSOR BENJAMIN MOORE.

Sir EDWARD SHARPEY SCHAFER, F.R.S., Professor of Physiology in the University of Edinburgh, writes: There is an error in your obituary notice of the late Professor Benjamin Moore which ought not to pass uncorrected. Dr. Moore was not a pupil of Sir William Ramsay, nor was he ever on the staff of the Chemical Laboratory at University College. Ramsay was, however, well aware of his attainments and, as he to me himself, was struck with his profound knowledge of chemistry. This knowledge Moore obtained from the late Professor Edmund Letts of Belfast, of whose teaching I always spoke with enthusiasm. Moore came from Belfast University College to study medicine, and after obtaining his qualifications was for five years my assistant in the department of physiology there. During that time he published important work, alone and with others, on the chemistry of the suprarenal capsules, on the physiological action of certain alkaloids, on the absorption of fats, and on the innervation of the spleen; building up so fine a reputation not only in biochemistry but also in experimental physiology that I was invited to occupy the Chair of Physiology in the Medical School of Yale University. The rest of his career was correctly given. By his premature death physiology has been deprived of one of its most distinguished exponents, and British physiologists have to deplore the loss of an able fellow worker, whose loyalty and modesty of character endeared him to his many friends, and not least to myself.

WE regret to record the death of Dr. WILLIAM HOLDER, J.P., which took place at Hull, in his 74th year. He was born at Hull, where he was apprenticed to a surgeon, and received his medical training at the then Hull and East Riding School of Medicine. He obtained the diploma of M.R.C.S. and the L.S.A. in 1872, and established himself in practice in Hull. He took a great interest in sanitary reform and was elected in 1888 to the Town Council, being elected an alderman in 1905, a position which he resigned in 1911 owing to ill health. He was chairman of the Sanitary Committee, and played a leading part in securing the removal of many of the city's worst slums; and he was an ardent advocate of cremation, inducing the Corporation to erect municipal crematorium, the first of its kind in the country. He was also chairman of the Electricity Committee, and persuaded the Town Council to embark upon the building of a power station and the installation of electricity. For over forty years he was an active member of the British Medical Association; he was a former chairman of the East York Division, and president of the East York and North Lincolnshire Branch. For many years Dr. Holder was one of the most energetic and prominent public men of Hull, held in high regard for his strength of character and his impartial mind. He is survived by his widow, two sons, and three daughters.

Dr. JAMES HURLEY died on March 5th at Newport (Mon.) where he had practised for the past thirty years. He was a native of Co. Cork, studied in Queen's College, Cork, and qualified L.R.C.S. and P.Ed. in 1890. After he settled in Newport he soon attracted a large number of patients, and had one of the most extensive general practices in the district. He held the appointments of medical officer and public vaccinator under the Newport Board of Guardians and medical officer to the Shipping Federation. Dr. Hurley was a member of the British Medical Association, but did not take an active part in medical politics. He was much devoted to sport, was a great lover of horses, and on more than one occasion obtained awards at the trial for hunters in connexion with Lord Tredegar's show. A colleague writes: "Hurley's death occurred with tragic suddenness. He attended as usual to his patients on Saturday, and was found dead on Sunday morning. One may reflect with the poet Horace of the uncertainty of life (*Odes iv, 7*):

"Quis scit an adjiciant hodiernae erastina summae
Tempora di superi?"

In a note contributed to this column of March 4th, p. 372 Dr. Herbert E. Friend said that the Rev. Dr. James George "must surely have been the last of the old army surgeon who saw service in the Crimean war." A correspondent writes: A War Office *Quarterly Army List* of last year shows six retired officers of the Army Medical Department, who served in the Crimea, as alive less than a year ago. Two of these have since died, but apparently there are four still

MISS KATE C. GARRICK, daughter of the late Sir James Francis Garrick, K.C., for ten years Agent-General in London for Queensland, has by her will bequeathed £10,000 to the Senate of the University of Queensland to found a James Francis Garrick professorship of either law or medicine, as may seem best to the University, in memory of her father.

THE Board of Control has, with the approval of the Minister of Health, appointed the following Committee to consider the nursing service in county and borough mental hospitals, and in what directions it can be improved: Dr. C. Hubert Bond, Commissioner of the Board of Control (chairman); Dame Louise Samuel, Mrs. How-Martyn, Mr. E. A. Medus, Dr. H. Wolseley-Lewis (Medical Superintendent, Kent County Mental Hospital, Maidstone), and Dr. G. F. Barham (Medical Superintendent, London County Mental Hospital, Claybury). The name of a matron of a mental hospital is to be added.

A POST-GRADUATE course in obstetrics will be held at the Clinie Baudelocque, Paris, from April 25th to July 13th. The subjects will include the pathology of gestation and parturition, pathology of the newborn, obstetrical operations, gynaecology, and syphilis and its relation to the functions of reproduction. The fees for the different parts of the course and further information may be obtained from the Secretary of the Faculty of Medicine, Rue de l'Ecole de Médecine, Paris.

THE thirty-fourth annual meeting of the American Pediatric Society will be held at Washington on May 1st, 2nd, and 3rd.

THE College of Ambulance can supply a motor ambulance equipped with x-ray apparatus and staffed by a radiographer, nurse, and bearers for use where a patient cannot be transported. It is free to the poor, and the fees charged to others can be obtained, together with all other particulars, on application to the College of Ambulance, 56, Queen Anne Street, Cavendish Square, W.1.

LOUVAIN University has received a legacy of £20,000, which is to be used for erecting a special building for cancer research.

AN epidemic of alastrim is reported to have spread all over the island of Jamaica; 2,300 cases have been reported during ten months, the epidemic having started in Kingston. Alastrim resembles a mild form of small-pox, and is thought to have originated in Brazil. Its occurrence has been reported in Cuba, Australia, and Canada during the past ten years.

THE Council of the Royal Sanitary Institute has established an examination in tropical hygiene for sanitary inspectors, the syllabus of which has been prepared to cover the special duties, including mosquito prevention, sanitation of native quarters, tropical conditions on health, tropical diseases, and has received the general approval of the Colonial Office and the London School of Tropical Medicine.

RECRUITING has been opened for the 8th (London) Sanitary Company, the establishment of which embraces a large proportion of N.C.O.s as inspectors. The course of training includes instruction in theoretical and practical sanitation, in addition to ordinary Territorial Army training, which includes fifteen days in camp annually, but the camp training may be excused. Application should be made to the O.C. 8th (London) Sanitary Company, Duke of York's Headquarters, Chelsea, S.W.3, any Monday or Wednesday between 6 and 8 p.m.

DR. H. S. COOPER, on the occasion of leaving Tuxley, where he has practised for twenty-two years, has been presented by his friends and patients with an illuminated address, a gold-mounted umbrella, and a tortoiseshell-handle walking stick. At the same time Mrs. Cooper was given a gold and amethyst brooch.

A GENEROUS gift has enabled the authorities of the Western Infirmary, Glasgow, to nominate a member of the nursing staff to take the course of training at King's College for Women (University of London) to qualify as a sister tutor.

AT Keighley West Riding Court, on March 4th, an ironworker was summoned by Dr. J. C. Wilson, of Haworth, for assault. Dr. Wilson had attended the man's child, who died of diphtheria, and a week or two later Dr. Wilson was stopped in the street by the man, who used abusive epithets to him and assaulted him. The defendant, in court, withdrew the allegations of negligence, and was bound over to be of good behaviour for twelve months. The chairman said that the magistrates thought Dr. Wilson had acted very generously in the matter.

AT their last meeting the governors of the Royal Bucks Hospital, Aylesbury, accepted with regret the resignation of Dr. Herace Rose from the position of surgeon-in-ordinary. Dr. J. Steele of Aylesbury was elected in his place, and Dr. Rose, in view of his length of service, was elected honorary consulting surgeon.

THE number of deaths from influenza in the week ending March 11th in the 105 great towns was 201, against 306, 525, and 670 in the preceding three weeks; in London the figures were 30, against 49 in the week ending March 4th. Thus the number of fatal cases from the disease continues to decline.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CONTRIBUTORS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

IN order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, Aitlokov, Westrand, London; telephone, 2630, Gerrard.

2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), Articulate, Westrand, London; telephone, 2630, Gerrard.

3. MEDICAL SECRETARY, Medisecra, Westrand, London; telephone, 2630, Gerrard. The address of the British Medical Association is: Medical Association, 11, Bedford Square, W.C.1; Baccilus, Dublin 6, Rutland Square, Dublin; telephone, 4361, Central.

QUERIES AND ANSWERS.

DIET AND GALL STONES.

DR. F. D. SPENCER (Wolverhampton) asks whether anything is known of a special diet for a patient who is constantly making gall stones. The suggestion is that as all gall stones are composed of cholesterol it should be possible to eliminate from the diet food that is likely to produce cholesterol.

TREATMENT OF TREMOR.

"W. G. W." desires suggestions as to any medicinal or other means for the alleviation of tremor of the right hand and foot in a lady, aged 77, who has been subject to the condition for some six or seven years. It is thought to be due to very slowly advancing paralysis agitans. There is no tremor elsewhere, nor other signs of the condition, and beyond some senile degeneration of the myocardium she is in good health and unduly active for her age.

CATHETER LUBRICANTS.

"X. Y. Z." would be much obliged if any member would inform him of the proper and safe strength of a cocaine lubricant or ointment (or allied preparation) to be used to smear on a catheter or bougie which has to be retained in the bladder for hours and causes great irritability. The case is one of stricture—where immediate dilatation or operation is not advised.

MEDICAL BOOK-KEEPING.

"SEEKER" writes to inquire if any medical practitioner who has evolved a complete but labour-saving system of keeping accounts and medical records of private work in general practice would describe it. He states that in looking for a practice he has seen many varieties of system, or lack of system, from the most meagre to an elaborate card-index system which apparently required far too much time and attention; moreover, the latter did not yield quickly a record of the work and income for a short period.

TREATMENT OF BROKEN CHILBLAINS.

DR. G. H. WAUGH (Rugby) writes: In answer to "J. B." (p. 420), the best treatment is sterilized gauze soaked in a mixture of equal parts of liq. plumbi sub. fort. and glycerin, changing the dressing as often as necessary on account of the discharge from the raw surfaces.

INCOME TAX.

"COUNTRY PHYSICIAN" lodged a claim to repayment of income tax with the local inspector of taxes. Later he was informed that a fire had occurred in the office in which the claim and documents had been destroyed, and more recently has been told that the duplicate claim which was then sent in had not been received.

* We suggest that our correspondent should request the inspector to obtain if possible special authority from the Board of Inland Revenue to repay the amount due without a formal claim, but after production by the solicitors who dealt with the claim of their record of the particulars. It might possibly save some further delay if the request was made direct through the Head Office of the Inland Revenue in Dublin. We have not heard of a similar case, but seeing that two claims have been destroyed or lost in transit we think that in the special circumstances repayment might be made without further expenditure of time and labour on preparing formal statements and vouchers.

"P. R." bought a 14.3-h.p. Austin car in 1915, sold it for £400 in 1921, and bought a 15.9-h.p. Wolseley for £930. What can he claim as an expense for income-tax purposes?

"The amount that can be claimed is the cost of replacement—that is, the expenditure incurred in obtaining a car of similar grade and power. Suppose, for instance, that a reasonable estimate of the cost of a 14.3-h.p. Austin car of 1921 (if there had been such a car) is £700, then the amount to be claimed is £700—£400=£300. The crux of the whole question is the fixing of the estimate for which £700 has been taken in the illustration above.

"FOREIGN" is living and domiciled in Egypt but has an income of £.0 from shares in the United Kingdom, which is taxed by deduction at 6s. in the £.

"He is entitled to such repayment as will result in his receiving a proportion of the normal income tax allowances, that proportion being determined by the ratio of his taxed income to the whole of his income whether liable to tax or not. Claims should be addressed to the Chief Inspector of Taxes (Claims), Cecil Chambers, Strand, London, W.C.2.

LETTERS, NOTES, ETC.

INTESTINAL DISINFECTION IN ENTERIC FEVER.

PROFESSOR JOHN EYRE, M.D., writes from the Bacteriological Department, Guy's Hospital: I am interested in a memorandum by Dr. Francis in the JOURNAL of March 11th (p. 388) regarding "dimol" in enteric fever, as for some time past I have been observing the results following the administration of this preparation upon the streptococcus found in the faeces (on the whole very satisfactory results have been obtained); but I have noted that in cases where pancreatic secretion was deficient the coated tabloids were not dissolved and were passed intact per rectum. The inference to be drawn from the last sentence of Dr. Francis's letter is that coated tabloids were used. Assuming that the intestinal haemorrhage was proper and not merely *post hoc*, is not the effect probably a purely mechanical one—congested areas (for example, Peyer's patches) being actually injured by the passage of the unaltered tabloids? Whereas the administration of 12-gram doses, which would involve the cutting in half of a tabloid and so enable solution to take place, was without effect.

DR. RONALD E. FRENCH (Burgh Heath, Surrey) writes: In your issue of March 11th, p. 388, Dr. T. E. Francis suggests that dimol may not be as free from irritation as the advertisement states; he got intestinal haemorrhage in two out of five cases of enteric within forty-eight hours of starting the administration of the drug, and found that the haemorrhage quickly ceased on discontinuing it. I have had a large experience in giving dimol to a considerable variety of cases, including one of enteric and one of acute streptococcal colitis with haemorrhagic stools, with, so far, no indication of its causing discomfort or irritation of the intestinal mucous membrane. I have always used the sugar-coated pulvrette A or the syrup of dimol. It would be interesting to know if Dr. Francis used the keratin-coated pulvrette B. If he did, I would suggest that the haemorrhage in his cases was much more likely to be caused by injury from the passage of the partially dissolved husk of the pulvrette than by irritation from the dimol.

DR. DAVID WALSH (London, W.1) writes: The communication of Dr. Francis describing five cases of enteric fever treated by a new antiseptic is of interest. Among other things it probably indicates the ideal method of the future in attacking that curiously localized infection *in situ*. Dr. Francis's report, however, appears to me inconclusive as a clinical experiment, inasmuch as (1) it deals with too small a number of cases; (2) the selected cases are those of relapse after crisis, where one might reasonably expect haemorrhage; (3) details of the haemorrhage are not given. A sounder clinical experiment, I venture to suggest, would be to treat a large number of cases with the given antiseptic from the outset of the disease and to compare results with control cases under ordinary treatment. In that way it is possible that clinical conclusions of great value might be arrived at.

"THE DROPPED SHOULDER SIGN."

"S. M. L." writes: At a recent school medical inspection a boy of 8 years was brought before me by the teacher on account of "dropping" of one shoulder of one or two months' duration. The attitude was evident at once, and a request to walk up and down showed a well-marked "drop" of one shoulder with inversion of the arm and hand (the latter held close to the body), somewhat suggestive of Erb's paralysis. The boy looked healthy, although of the lowest class socially, and I requested that he be stripped for closer examination. Removal of the jersey at once revealed the cause of the abnormality; the nether garment had for its only support a single brace-strap over one shoulder, fixed at either end with a safety-pin. One limb of the garment was left to look after itself, and the peculiar, and at first sight morbid, attitude and gait had been adopted owing to a feeling of insecurity. The sartorial outfit comprised jersey, pants, cotton shirt, and socks (this in February), and not a button amongst them.

RESUSCITATION AFTER APPARENT DEATH.

DR. P. VERNON DODD (Ilythe) writes: The interesting article by Dr. Armstrong in the BRITISH MEDICAL JOURNAL of January 28th, 1922, p. 141, with notes on the heart beating under stimulation for some time after (apparent) death reminds me of a somewhat similar occurrence in the heart of a fish after death. I was sea-fishing in an open boat on a rough winter day, with a freezing east wind blowing and sleet falling. I caught a good-sized whiting which had swallowed the hook. As there was some difficulty in extracting it I cut the fish open, and on wrenching out the hook the heart was forced out with it and fell on the snow on the seat in front of me; although it was separated from the body I watched the detached heart beat regularly for twenty minutes. I suppose the exciting cause was the stimulation of the cardiac ganglia by the cold wind. In the case of the woman referred to by Dr. Armstrong could not the heart, which is stimulated into action and kept going by the blood during life, have been stimulated into action and kept going after death by the direct action of the drugs (which in this case were injected into the left ventricle) stimulating the cardiac ganglia? It is quite possible that lives may be saved, in healthy persons who have collapsed and become apparently dead after an anaesthetic, by the immediate and systematic injection of adrenaline or some other drug into the left ventricle even before resorting to artificial respiration.

UNUSUAL FECUNDITY.

DR. J. R. WATSON (Hamilton, Lanarkshire) writes: This week I attended a twin birth in the case of a Mrs. A., whose present age is 34. She was married sixteen years ago, and in that time has given birth to 19 children. The sequence of the births is as follows: four single male children; twins, both male; twins, both female; triplets, two male and one female; three single female children; one single male; twins, both male; and lastly, twins, both male—a wonderful record for a woman of 34. All the multiple births were premature. Only four remain alive, one boy and three girls, all four being particularly fine children. There is a history of twin births in both the father's and the mother's family.

FREE INSURANCE.

AN ingenious skit, entitled "Our Free Insurance Scheme," appears in the March number of the *St. Bartholomew's Hospital Journal*. "Doctors," it begins, "are liable to suffer from many complaints; we cannot insure against all of them. We have thought it out carefully, and have picked out the following diseases, which can be insured against in no other journal. All ages do not suffer from the same complaints, and we therefore divide our readers into three classes: (1) The very young (aged 1 to 12); (2) the middle-aged (aged 13 to 50); (3) the very old (aged 51 to infinity). Class 1.—The very young will receive £5 on dying from, and 5s. a week (up to three weeks) if suffering from, any (or all) of the following: Angina pectoris, carcinoma of the prostate, hydatidiform mole, Parkinson's disease, alcoholic neuritis, and pseudocyesis. Class 2.—The middle-aged will receive £2 on dying from, and 2s. a week (up to two weeks) if suffering from, any of the following: Amyotonia congenita, psammoma of the left kidney, Rocky Mountain fever, Recklinghausen's disease, fracture of the bundle of Vieq d'Azyr, and weaver's bottom. Class 3.—The very old receive 2s. 6d. on dying from, and 3d. weekly (up to a maximum of one week) if suffering from, any of the following: Teething convulsions, anencephaly, congenital stenosis of the pylorus, von Jaksch's anaemia, intussusception, and paramumps. It will be seen that these diseases have been chosen with two ends in view: (1) The diseases must look very well on paper. (2) There must be no chance of this journal's having to pay out any money (which would be a most wasteful proceeding)." We commend the idea to our contemporaries.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 28, 29, 32, 33, and 34 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 30 and 31.

THE following appointments of certifying factory surgeons are vacant: Frieckheim (Forfar), Huntingdon (Huntingdon).

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 423, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive *posto restante* letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

249. Treatment of Rickets by Starvation.
McCORMICK and NINA SIMMONDS (*Johns Hopkins Hospital Bulletin*, January, 1922), continuing the studies on experimental rickets, give the results of their observations on the effects of starvation on the healing of rickets. Young rats were fed on a restricted diet for thirty to forty days until rickets was produced. This diet contained a liberal amount of good quality proteins and about twice the calcium necessary for optimum growth and nutrition. It is low in fat-soluble A vitamin, and below the optimum in its content of phosphorus. When young rats are fed on this diet they develop a condition of the skeleton identical with that in the rickets child, so that the cartilage and adjacent portion of the metaphysis in the long bones are entirely free from calcium salts. If 2 per cent. of cod-liver oil is now administered with this deficiency diet calcium salts are deposited in the cartilage on the epiphyseal side of the metaphysis. Schmorl and others have proved this reappearance of the provisional zone of calcification to be the beginning of the healing of the lesion, and it usually appears within five days of the addition of the cod-liver oil to the diet. Having produced rickets in young rats by the above process the authors subjected them to starvation for a period of from three to five days. In every case the starved animals showed reformation of the provisional zone of calcification and other evidences of the healing of the rachitic process, while none of the controls, which had not been subjected to starvation, showed the slightest trace of calcium in the cartilage or metaphysis. Apparently starvation causes healing of rickets, just as do cod-liver oil and sunlight; but whereas the two latter improve the general condition, starvation causes the death of the animal in a few days. Hence starvation cannot be recommended as a desirable method of treating rickets in the human. These experiments provide proofs of the beneficial effects of starvation on the animal body. The authors' view is that when the load of a defective diet is removed and the body is forced to draw on its own resources, stored foodstuffs are released into the blood stream, and the healing of rickets which takes place may be due to the liberation of phosphorus from disintegrated protoplasm (for example, muscle tissue), which causes calcium deposition in the cartilage.

250. Treatment of Ringworm of the Beard.
RAYAULT and BOULIN (*Ann. de Derm. et de Syph.*, January, 1922) bring forward fresh evidence of the value of intravenous injections of Lugol's solution in tinea sycosis, on the merits of which they have previously reported. Treatment in the present case was commenced twenty days from the first manifestation of the disease, and a complete cure was effected in fifteen days. No antisepsies were used locally, the only form of medication being Lugol's solution (iodine in potassium iodide solution), which was injected intravenously daily, commencing with 1 c.cm. and increasing by the same amount each day up to 5 c.cm., the maximum dose. Improvement showed itself immediately after the first injection, and by the eighth day the lesions showed signs of cicatrization. By the fifteenth day there was no trace of the fungus in any of the hairs examined. The authors maintain that Lugol's solution is of much greater value when administered intravenously than is potassium iodide alone. The disadvantage of the local reaction caused by Lugol's solution is overcome by diluting the injection with serum, or by aspirating blood from the vein and mixing it with the fluid in the syringe before injecting.

251. Typhoid Fever Complicated by Bacillus aerogenes capsulatus Infection.

A somewhat unusual type of complication in the course of typhoid fever is described by Muller and Lincoln (*Med. Record*, February 4th, 1922). A white man, aged 29, was admitted to hospital at the end of the second week of typhoid fever. Examination showed the spleen to be enlarged; a diffuse macular rash over the chest and abdomen which did not disappear on pressure, a white cell count of 2,400 per c.mm., and a temperature of 104°F.; the Widal reaction was positive and the blood culture negative. Three days after admission he became restless, dyspnoeic, and cyanotic, the pulse became rapid, and an area of subcutaneous emphysema about the size of the palm of the hand was found in the right anterior axillary region. A blood count showed a leucocytosis of

23,400 whites, with a differential count of 63 per cent. polymorphs, 29 per cent. lymphocytes, and 11 per cent. large mononuclears. The same evening the patient died. At autopsy the tissues, somatic and visceral, were found to be riddled with gas bubbles. In the small intestine typical typhoid ulceration was encountered. A bacteriological examination of the spleen resulted in the demonstration of the *B. typhosus* and of a Gram-positive anaerobic organism with the morphological and cultural characters of *B. welchii*. There seems to be little doubt in this case that the gas-producing organism had gained entrance to the tissues before death, and it is probable that invasion had occurred through one of the ulcers in the intestine. It is interesting to notice how this case confirms the observation of Flexner that life is impossible after this organism has once established itself in the blood and produced gas there. It is on this account that extensive subcutaneous emphysema is not found in the patient before death.

252. Pulmonary Tuberculosis and Intestinal Stasis.
MORRISTON DAVIES (*Tubercle*, February, 1922) finds that, in a considerable proportion of cases, rises of temperature in the subjects of pulmonary tuberculosis are the effects of intestinal stasis. His chief guide to the severity of intestinal stasis is the urine, and frequent examinations for amino-acid derivatives convinced him that the frequency of skatolyl in patients suffering from tuberculosis of the lungs is great, and that drugs, such as castor oil and calomel, which combat intestinal stasis often act like a charm on these patients. He found the presence of acetone in the urine much commoner than he had imagined, and the symptoms it produced were easily abolished by large doses of sodium bicarbonate and potassium citrate. He always found the urine contained a considerable quantity of the amino-acid derivatives when the patient was suffering from a short bout of fever with nausea, coryza, and bronchitis. One patient, whose progress was constantly being interrupted at intervals of about six weeks by these attacks, had been immune from them for over a year after he began to dose himself with castor oil at the first sign of an attack. In some cases a previously steady temperature rises slowly to a slightly higher level each night and morning, the patient feeling "off colour" or more tired than usual. If the fever is due to intestinal stasis the urine shows an increase in the sulpho-ethers, and the temperature returns to its old level after free purgation. But when there is no change in the character of the urine in association with this rise of temperature, it is probably due to the tubercle bacillus. For continued administration the author has found kaolin, paraffin, agar, dimcol, and salol the most satisfactory.

253. Treatment of Paralysis Agitans by Intramuscular Injection of Magnesium Sulphate.

ARTAUD DE VEYEX (*Bull. Soc. de Thér.*, November 9th, 1921), having observed that the subjects of paralysis agitans almost invariably suffer from chronic constipation even before the onset of the nervous symptoms, is inclined to attribute an active part in the etiology of the disease to the toxic action of intestinal ptomaines on the nerve centres. He has recently treated eight cases of paralysis agitans with intramuscular injections of 25 per cent. solution of magnesium sulphate. In all the cases, even those of long standing, the treatment was followed by a diminution of the tremors and improvement of the general condition, although a complete cure was effected in only two cases, in both of which the treatment had been instituted at an early stage of the disease. Apart from diarrhoea there is no contraindication to the treatment, and no complication is to be feared provided the injections are given aseptically.

254. Novasurrol as a Diuretic.

HASSENCAMP (*Zentralbl. f. inn. Med.*, February 11th, 1922) draws attention to the great value of a diuretic, novasurrol, especially in the oedema of heart disease. He points out that the diuretic action of mercurry, used mostly as calomel, has long been known. But through the frequent undesirable effects of mercury its use as a diuretic has been much restricted. Novasurrol was first used as a diuretic by Poelen and Lange, and a number of observers have confirmed their results. Novasurrol is a combination of an organic salt of mercurry and sodium with veronal. It contains 33.9 per cent. of mercurry, and is sold in sterile ampullae containing 2.2 c.cm. of a 10 per cent. solution. It may be injected

into the gluteal region or intravenously. In the normal condition it has no marked diuretic action; in pleurisy, peritonitis, and ascites, the effects were unsatisfactory. In nephritis, owing to the injurious action of mercury on the kidneys, the author has not ventured to try it. Its chief use is in the oedema of cardiac disease, where the drug has an excellent effect. Usually 2.2 c.cm. were injected intravenously, but in cachectic cases only 1.1 c.cm. Generally intervals of two or three days were allowed between the injections. Diuresis begins in two or three hours and ends after ten to twenty hours. In twenty-four hours, 2, 3, or more litres of urine are excreted. Results are obtained in almost all cardiac cases, but in varying degrees. A case of mitral disease with very marked oedema is recorded, in which diuresis and rapid disappearance of the oedema followed the use of the drug on several occasions.

255. Prognosis in Heart Disease.

MOON (*New York Med. Journ.*, January 18th, 1922) considers that, from the point of view of prognosis in heart disease, it is more important to decide whether a lesion is of rheumatic or arterio-sclerotic origin than to know which valve is affected. Prognosis is better in those of rheumatic origin because the lesion tends to become stationary, whereas in the arterio-sclerotic cases the lesion is progressive; but in young children, even though of rheumatic origin, the outlook is serious because of the frequency with which the pericardium and myocardium are also involved. Mitral stenosis with reasonable care may carry on for several years, but when once the heart has begun to fail compensation is less easily restored than in mitral regurgitation. Atrial fibrillation is most likely to supervene in cases of mitral stenosis, rendering the prognosis serious; but by the use of digitalis and rest these cases may live on for years if it is possible to avoid exhausting the myocardium by lessening the frequency of the ventricular contractions. The prognosis in mitral regurgitation is good owing to its amenability to treatment, and especially if the hereditary history is that of a long-lived stock. In aortic disease of rheumatic origin the prognosis is good, apart from the risks of later attacks of rheumatism, both from the point of view of length of life and with regard to the amount of work which can be done. A guarded prognosis should be given in aortic disease of arterio-sclerotic origin on account of the liability to sudden death.

256. Sulphur Injections in Chronic Arthritis.

II Morgagni (December 25th, 1921) draws attention to the favourable results obtained in chronic arthritis by gluteal injections of a 1 per cent. solution of sulphur in olive oil. The immediate results are unpleasant: a good deal of pain and swelling of the joint, fever, and troublesome vomiting—very much the same group of symptoms as follow helio-protein injections. But unless this reaction takes place no good effects on the arthritis can be expected. MOLNAR publishes some cases where his sulphur treatment gave good results, enough to warrant further trial. The dose of the solution injected is from 3 to 10 c.cm. at weekly intervals.

SURGERY.

257. Sedimentation of Erythrocytes as an Aid to Surgical Diagnosis.

FROM a study of the sedimentation velocity of the red blood cells in 700 surgical cases LÖHR (*Zentralbl. f. Chir.*, 1921, 35) concludes that all inflammatory conditions, in spite of varying origin and intensity, are accompanied by an acceleration of the sedimentation rate, more marked, as a general rule, in the more acute and more extensive inflammations. After sterile wounds, and after uncomplicated simple fractures, a gradually increasing rate becomes manifest at about the twelfth hour, returning to normal with the occurrence of fibrous or bony union respectively. In patients suffering from benign tumours the rate is unaltered, but all tumours of malignant nature are associated with an increased sedimentation velocity, which seems proportional to the size of the neoplasm and to the rapidity of its growth. After x-ray treatment of tumours the rate is diminished in accordance with that of the shrinkage of the tumours. Parenteral injections of foreign proteins—for example, casein, horse serum, and tuberculin—are followed by accelerated sedimentation and velocity. Applying his findings to surgical diagnosis, the writer concludes that estimations of the sedimentation rate are of service in the differential diagnosis between inflammatory and non-inflammatory swellings, especially in distinguishing chronic tuberculous disease of joints from non-inflammatory joint conditions. They do not serve, however, any useful purpose in cases in which the diagnosis lies between an inflammatory and a malignant neoplastic

258. Unusual Injury to Back.

ELLIS (*Journ. Royal Naval Med. Service*, January, 1922) records a case of injury to the back presenting some unusual features. An able seaman, aged 24, felt something "give" in his back while playing football, but which did not prevent his continuing the game, nor produce any symptoms until five days later, when a swelling rather larger in circumference than a five-shilling piece appeared in the course of a day over the junction of the lumbar and sacral vertebrae. There was never any bruising or discoloration of the skin, and there was only slight tenderness on palpation, but stretching of the deep spinal ligaments and muscles by bending forwards caused pain. The swelling decreased a little in size so that the upper border of the sacrum became palpable. The man was able to move and walk about freely, and a diagnosis of haematoma, following partial rupture of the spinal ligaments, was made and subsequently confirmed by x rays, which showed no abnormality in the spine. The swelling absorbed spontaneously without any pain, stiffness, or other ill effects. The length of time elapsing before the swelling became evident, the absence of all acute pain, bruising, or external signs of injury, pointing to the fact that the haematoma resulted from a sudden twisting rather than from direct violence, and the comparative freedom of movement in the spine after the haematoma had formed, are the main points of interest.

259. Congenital Insufficiency of the Abdominal Muscles.

PAUZAT (*Gaz. hebdom. des Sci. méd. de Bordeaux*, December 4th, 1921), in his Bordeaux thesis states that congenital insufficiency of the abdominal muscles is a definite affection, presenting the following characteristics. It is peculiar to the male sex. Malformation of the abdominal wall, such as more or less complete absence of muscular tissue, and excessive development of the abdominal wall, may occur alone or be associated with malformation of the urinary system (hypertrophy and dilatation of the bladder and ureters) or genital system (testicular ectopia). The most frequent form met with clinically is that in which muscular insufficiency of the abdominal wall is associated with malformation of the urinary tract and genital ectopia. The diagnosis is easy except in the slight forms; isolated muscular insufficiency is comparatively rare. The prognosis is good as regards life, but bad as regards function in the absence of treatment, as recovery does not take place spontaneously. Treatment consists in making the patient wear an abdominal belt.

260. Gall-Bladder Lesions.

EINHORN (*Med. Record*, December 10th, 1921) records three cases of gall-bladder lesion in which the symptoms simulated other affections of the digestive tract. In the first, a woman, aged 50, suffered from vomiting directly after food, with hunger pain, loss of weight, and a feeling of obstruction on swallowing; but the duodenal bucket-string test and gastric analysis showed the presence of cholesterol and calcium bilirubin crystals, etc., pointing to gall-bladder disease. The second case, a man aged 51, complained of symptoms suggestive of duodenal ulcer, hunger pains, and severe attacks of gastralgia with long periods of intermission. Both the string test and the examination of the bile pointed to gall-bladder disease, which was confirmed at operation. The third case, like the others, gave no symptoms of gall-bladder mischief, and had been diagnosed as intestinal obstruction, but direct examination of the bile pointed to cholecystitis probably due to stone, and there was tenderness over McBurney's point. Operation confirmed the diagnosis of cholecystitis and chronic appendicitis. These cases show the importance of direct examination of the bile, the essential points in gall-bladder lesions being turbidity of the fresh bile, and the presence of mucus, pus, bacteria, and cholesterol and calcium bilirubin crystals; the presence of large cholesterol crystals indicating the presence of stones, though numerous crystals can occur in cholecystitis without stones.

261. Spontaneous Rupture of the Epigastric Artery.

KOTZAREFF (*Lyon Chir.*, September-October, 1921) states that rupture of the epigastric artery may be traumatic or spontaneous. The result of the rupture is a haematoma of more or less considerable size, which may simulate several abdominal affections, especially those of the internal generative organs. In spontaneous rupture, of which the writer records an example, the artery on the right side is almost always affected. The cases may be divided into two groups—namely, those which present general vascular disturbances, either congenital or acquired, and those in whom these disturbances are exclusively local and almost always acquired. Arterial hypoplasia, generalized arterio-sclerosis, and chronic arteritis, which may be of syphilitic, alcoholic, or infective origin, are the usual causes of general vascular disturbances.

But it is undoubtedly possible for one of these causes to be localized in a single artery such as the epigastric. As a rule the symptoms are vague, and bear some resemblance to those of appendicitis, inflammation of the adnexa, or an ovarian cyst. The physical signs are more definite, especially if the haematoma has reached a certain size. There is then an infiltration of the superficial layers of the region, and sometimes cutaneous coehymoses. The haematoma is only slightly movable. The swelling of the abdominal wall is well circumscribed, and not developed at the expense of the skin. Gynaecological disorders can be excluded by vaginal or rectal examination. Treatment may be either conservative (compresses and rest in bed) or, as Kotzareff himself recommends, operative—namely, ligation of the torn artery, which will prevent any relapses or complications.

267. Cholelithiasis and Carcinoma of the Gall Bladder.

MARCHAND (*Wien. Klin. Woch.*, December 15th, 1921), commenting on von Aldor's paper (vide EPITOME, December 17th, No. 580), states that among 136 cases of carcinoma of the gall bladder examined at the Leipzig Pathological Institute from 1900 to the middle of 1921 no less than 110, or 80 per cent., showed biliary calculi, 26, or 23.6 per cent., of the cases being in men and 84, or 76.3 per cent., in women. Of 32 cases of cancer of the bile ducts only 6, three of which were in men and three in women, were associated with gall stones. Marchand maintains that, with rare exceptions, carcinoma of the gall bladder is always associated with a present or past cholelithiasis. This does not mean, however, that carcinoma cannot arise without gall stones, as in cancer of the large bile ducts calculi are absent in most cases. The question whether gall stones are primary or a causal factor in the development of cancer, or whether they develop as the result of carcinoma of the gall bladder, can usually be easily decided by the anatomical condition, though occasionally doubtful cases may arise. The not infrequent examples of carcinoma in which stones are not to be found are chiefly those in which fistulous connexions with neighbouring organs exist, especially the duodenum, caused by ulceration due to gall stones. Marchand points out that carcinoma of the gall bladder is one of the best examples of the development of a malignant growth from pre-existing lesions due to other causes. Its prevalence in the female sex is explained by the much greater frequency of gall stones in women, which in many cases is undoubtedly due to mechanical causes (fashion in dress). The same factor is also not infrequently present in men, as in pressure of the costal arch through constant sitting and a low position of the liver.

263. Local Use of Acetyl-salicylic Acid.

HELLER (*Therap. Gazette*, December 15th, 1921), from the experience of 1,000 cases convalescent from tonsillectomy, advocates the local application of acetyl-salicylic acid after tonsillectomy, and in acute pharyngitis, for the relief of dysphagia; 1 to 3 decigrams ($\frac{1}{2}$ to $\frac{3}{4}$ grains) of the powdered drug are given on the tongue eight to ten hours after operation, and repeated ten to fifteen minutes before each meal for three or four days. Relief is almost universal, swallowing being comfortable immediately the powder has passed the oropharynx. A weak solution (3 decigrams to 50 c.cm. of water) may be used as a gargle with practically the same result. In acute pharyngitis or tonsillitis similar results are obtained if 1 to 3 grains are placed on the tongue without water every three or four hours. The effect is produced by its local action and not by the septicæmic effect of the drug.

261. Hereditary Optic Atrophy.

FORIET (*Med. Journ. of Australia*, December 3rd, 1921) calls attention to the possible menace to the community of hereditary optic atrophy. Arising usually a few years after puberty as a retrobulbar neuritis with the development of a large incurable central scotoma, the vision becomes dim, colours indistinguishable, and, though never ending in total blindness, it may be so defective that the patient has to be blind about. Treatment avails nothing, but the condition tends to improve, though not to any great extent. The condition is hereditary, affecting the males through the females, who rarely suffer, and the danger of its dissemination by marriage is obvious; the only means of controlling its spread is by the affected families dying out. Particulars of one family are reported in which twelve already are affected; ten are boys at yet of the age for its development, and seventeen are unmarried girls, each capable of giving rise to freshly affected families. From one union twelve entirely distinct families have been affected, and, in sparsely populated Western Australia, the author believes that in twenty years the number of cases will have increased out of proportion to the increase in population.

OBSTETRICS AND GYNAECOLOGY.

265. Pregnancy and Tuberculosis.

ACCORDING TO STEWART (*Canadian Med. Assoc. Journ.*, January, 1922) it is indubitable that in the majority of cases the child-bearing cycle exercises, eventually, at any rate, a very unfavourable effect on the woman who has pulmonary tuberculosis. Although the early months of pregnancy may in certain cases show an improved maternal condition, the most fateful epoch for the mother begins with parturition. Of 200 sanatorium cases of child-bearing women, the lighting up of the tuberculous disease appeared to have occurred during a gestation in 25 per cent., in the first month post partum in 24 per cent., during the next twelve months in 36 per cent., and between successive cycles of pregnancy and lactation in 15 per cent. Similar findings have been reported by other observers. In the series referred to the first, second, and third childbirths seemed each to have been responsible for one-fourth of the breakdowns, pregnancies beyond the third for the remaining fourth. The deleterious effect of the child-bearing cycle is explained by—(1) mechanical factors: the gravid uterus constitutes a heavy burden, and, although pressure on the diaphragm and lungs may be beneficial, the removal of the pressure after labour is harmful by suddenly increasing the pulmonary motility (hence van Voornfeld recommends artificial pneumothorax as almost specific treatment in cases of pregnancy in tuberculous women); (2) the nervous strain of pregnancy, labour, and the care of the infant; (3) impaired nutrition during pregnancy as a consequence of nausea and vomiting; (4) the shock and haemorrhage accompanying parturition: the violent straining and respiratory efforts may tend also to force infective material from old into new pulmonary foci, as was shown by Hanan by observations made at autopsy. In answer to the question, "Should a woman known to be, or to have been, actively tuberculous ever risk maternity?" the writer remarks that pregnancy should not be allowed in a woman who has ever reached a stage anatomically "far advanced"—that is, the stage of the disease consistent with a very fair appearance and usually, though inaccurately, described as "early." Pregnancy should be forbidden in the presence of active symptoms, however slight, and thereafter for at least three years, or longer if the bacilli have ever been found in the sputum. For the many the old rule holds good that the tuberculous woman, should not marry or, if married, should not become a mother. In such a woman pregnancy may be allowed if the lesion, originally moderate in extent, has been arrested for from three to five years, during which the strength and resistance have been well and successfully tried, if economic circumstances are favourable, and if skilled medical supervision is available before and after birth.

266. Cancer of the Pregnant Uterus Treated by Radium.

DE ROUVILLE (*Gynec. et Obstet.*, 1921, iv, 5) relates the case of a woman, aged 35, who, in the fifth month of pregnancy, consulted him for severe dyspareunia. She was living. Examination showed a large, hard, irregular mass of the cervix with some parametrial thickening. The cervix measured 100 mg. of radium bromide was made for twenty-four hours. A month later the patient was prematurely delivered of a dead child, and a few days later the findings on vaginal examination appeared normal except for slight parametrial thickening. Siredey (*Ibid.*) records the case of a woman, aged 24, who complained of abundant haemorrhage and who was found on examination to exhibit signs of a two months' pregnancy and an indurated swelling of the anterior portion of the cervix which was proved microscopically to be an early carcinoma. A radium treatment of 22 millienries applied for twenty-four hours was followed by rapid amelioration of the symptoms and disappearance of the morbid clinical signs. Hysterectomy, which had been contemplated, was now felt not to be justified. Pregnancy continued for some time, but was terminated after the removal later of a second piece of tissue for the purpose of microscopical examination.

267. Treatment and Prophylaxis of Puerperal Fever.

HIESS and HIRSCHENHAUSER (*Zentralbl. f. Gynäk.*, February 11th, 1922) record their experiences in treating severe cases of puerperal fever by preparations of colloidal silver, of casein, and of iodine, given intravenously in each case. Injections of colloidal silver owe, it is said, any efficacy which they possess not to a bactericidal action but to the stimulation of tissue resistance by foreign protein injection. The authors find that while some severe cases prove refractory to this treatment, others respond by rapid fall of temperature and speedy improvement of general condition. As a rule the injections were given at intervals of one or two days, and in certain cases the first two injections appeared to be

In bringing to an end my long series of studies on this disease and giving it now this final name, may I note that by an interesting coincidence the disease this year celebrates the centenary of its first case recorded in any language—namely, that recorded by Combe of Edinburgh in 1822.

May I note further that the very first words he applied to the disease were: "A very peculiar disease, which will doubtless be viewed in different lights and receive different appellations. If any train of symptoms may be allowed to constitute anaemia a generic disease, the following may be considered an example of it in its most idiopathic form."

May I add, further, the final opinion of the oldest observer who had followed its story for a period of nearly sixty years—from its earliest beginnings in English medicine in the late "forties" of the past century to the final termination of my own work upon it in 1903. The observer referred to was Professor Sir William Gairdner of Glasgow (1903), who said, writing a year or two before his death:

"My earliest acquaintance with the disease dates from the late 'forties,' when I reviewed the first paper in which Addison introduced his idiopathic anaemia idea. All I have seen makes generally for your view of the case. I wish I had taken note of the glossitic phenomena you describe, but I am afraid I am among the number of those who have passed over very much within my view. If you can make that point (the glossitis) clear as being of the frequency you describe, you will have won your case against all gainsayers."

In introducing this name, may I, to save time, anticipate the criticism which I know from past experience of everything connected with the name "pernicious" will assuredly be raised. That criticism is that I have described a "new form" of pernicious anaemia, thereby only making confusion worse confounded. To anticipate this may I repeat that, apart from the disease to which I now give the name of "glossitic anaemia," I have never seen a case of "pernicious anaemia" in my life, or a case of "idiopathic anaemia of Addison," or a case of "Addisonian anaemia," or a case of "Addison-Hunterian anaemia."

What I have done is to obtain the great haemolytic disease in a pure form such as rarely, if ever, previously existed; to find that this disease when freed from sepsis has milder characters and a more benign and better course than it ever before had, and that it deserves some name that will help in its diagnosis and treatment, instead of the name "pernicious," which does neither.

May I also anticipate another kind of criticism which it may at once receive. It was once I heard recently from a student. He had evidently been taught to attach no importance to it, because, as he said, a similar sore tongue could also be found in sprue, scarlet fever, and leucoplakia! Sprue, a disease of which most people have never seen a case; leucoplakia, a condition which is of no vital importance to anyone; and scarlet fever, of which I have seen many thousands of cases, and with whose tongue conditions, it may be presumed, I am well acquainted. The sore tongue to which I attach importance is that found in combination with the twenty-one characteristic clinical features of the disease I term glossitic anaemia.

Sore Tongue Features in Ten Cases.

The sore-tongue lesions I refer to are those I described for the first time in the first case of the disease I ever studied (1890). Their histological characters are illustrated in my work on *Severest Anaemias* (1910), in plates which I now show you. Their constancy is such that I have seen them in every case—150 or more—of which I have full records. Their characters when marked are shown in the coloured plate from the last case under my observation. Their relation to the disease from its origin onwards may be illustrated by the following cases selected almost at random from my records.

CASE I. (The Original Case, 1889.)

Illness dated from the autumn of 1887. While on holiday in the country he was exposed for a time to unhealthy sanitary conditions—drain smells. He suffered at the time from sore tongue and sore throat, and never afterwards regained his health.

1887. He continued to suffer at times from an inflamed tongue—red spots on the tongue.

1888 (June). His tongue troubled him very much, tenderness on eating, extending down the throat into his stomach. Tongue extremely flabby, indented by the teeth, presenting a red fiery appearance, with scattered patches of a more inflamed character. Portions of the mucosa being smooth as if devoid of papillae. The redness extended to anterior pillar of fauces.

May, 1889. Tongue much the same as before, not quite so raw; along edges there are patches of more fiery redness. Some of these under tip of tongue show small inflamed vesicles full of serum. (Death took place in May, 1889.)

Case XII (1901). About September, 1900, very bad inflamed tongue, deep red. Swelled so that he could hardly get it out of his mouth, and had to take everything cold—anything warm gave him pain. Tongue always more or less tender for some years before—always on the same spot, the right side; with sometimes little vesicles. They came and went, but were never severe till September, 1900, when the attack lasted six weeks. Has not been troubled with it much till now (May, 1901), when it became sore all over and is still sore. It is now smooth and glazed. (Death, 1901.)

(Illustrations of this tongue in *Severest Anaemias* (1910), Plate 2, Fig. 4; Plate 5, Figs. 9 and 10. The changes were extreme in character, nearly all the muscle substance being destroyed, and the epithelial covering reduced to a mere line of cells.)

CASE XV (1901).

A gentleman, an eminent member of the profession, living retired in a large old country house with sporting estate attached. He was fond of gardening. In the autumn of 1900 he spent much time in watering his roses with sewage obtained from an old cesspool, the stench of which was very bad. His tongue became very sore, and at the same time he began to feel very weak and tired at the end of the day. He had formed a small sitting-room from a former gun-room, with which an old lavatory was connected. He used to sit, feeling very wearied, by the fire in this room, between the fire and the lavatory floor, so that, unknowing, he had again exposed himself to very marked drain infection. He became very ill and anaemic during the autumn (stage of invasion). He had all the features of pernicious anaemia the following spring when I saw him, accompanied by the recurrent sore tongue. He made a remarkably good recovery three months after I saw him, and enjoyed excellent and robust health over a period of eight years, when he died.

He wrote me that he still from time to time had feelings of intense illness, which gave him concern, and a feeling that he still had his old disease on him. I saw him only once, some six years later, in robust health. His tongue was beefy red and very characteristic. He died two or three years later, but I never got any further details.

CASE XIX (1901).

Month becomes sore every three or four weeks with what appear to be little "canker spots" on sides; tongue swells and cracks. This lasts about a week, then goes off for a time. January, 1902. Tongue much better, sores on sides healed, but surface shows a sodden appearance. February. Patches on side of tongue returning. March. Tongue better and clean. (Death. Illustrations tongue, op. cit., Plate 2, Fig. 3.)

CASE XX (1901).

Ill health began in 1893 when she went to stay with friends; slept in an insanitary room for a month. On returning home complained of a sore tongue (incubation period of disease; three to five weeks). It was swollen and raw, so that she could not be touch it, a number of ulcers—eight on one side alone—extended all round edges of the tongue, inside the cheeks, and on the tip. She has had this condition off and on ever since about every three weeks. Tongue now soft, with angry red patches or patches, like sodden blisters, very tender. Tongue at times up almost to teeth. February, 1902. Tongue very clean. March, 1902. Three red spots on tongue fit tip. On left yellow vesicles about size of a barley seed. Later on improved and no redness.

For last two years "she has always had a sore tongue she could not take wine without a feeling of scalding as stomach." It comes and goes; no vesicles, but little cracks appear on edges and on dorsum. Tongue has now a singularly inflamed look, with cracks all over the edges; great tenderness.

CASE XXVIII (1903).

Tongue became sore about three months ago (September); soreness seems to go right through to back passage. On left perfectly well for a time, then a relapse occurs once in two to three weeks. It has now a smooth and fissured appearance.

CASE XXXIV (1905).

Ill health began some four years ago (1901), when he had a severe attack of anaemia. Tongue has been sore off and on since 1901. Always noted at the times he is ill. Then the pain goes down pit of stomach, causing retching and indigestion; then he gets weak he has to go to bed.

CASE XLIV (1907).

Good health till spring of 1903, when she came in contact with a very foul drain. Tongue at this time began to be sore and varying in intensity and distribution; and this has continued to present time with periods of intermission.

CASE XLVII (1907).

Since 1905 tongue has been very sore—very beefy-looking. Sometimes blood raw. Comes and goes every few weeks. Soreness extends down into stomach, with severe diarrhoea. 1908. Tongue remarkable—bright, fiery red, with cracks on sides and bright red papillae all over. September. Run down in health and had a bad tongue. Tongue gets inflamed at tip every three weeks, accompanied by some discomfort in stomach and lower down, as if he were inflamed all the way down.

CAFFEINE (BISHOP)

(Each drachm contains One grain Caffeine Alkaloid)

— RELIEVES —

MORNING HEADACHE.

Clinical researches on the action of CAFFEINE show that:—

1.—More work can be done, and more easily done, when the drug is taken than when it is not taken.

2.—CAFFEINE does not cause any marked rise of blood pressure, and in small doses acts as a stimulant to the reflex muscles of the spinal cord.

3.—The stimulating effect of CAFFEINE begins about one hour after the dose when taken as BISHOP'S CAFFEINE.

4.—The effect of CAFFEINE on the acuteness of the senses has been demonstrated by the greater accuracy of touch under its influence.

BISHOP'S CAFFEINE is almost a specific in cases of Morning Headache, and is of unequalled efficacy in Mental and Nervous Fatigue, and Exhaustion and Heart Failure. It relieves all forms of headaches, including the Uræmic headache associated with long established kidney complaints.

BISHOP'S CAFFEINE presents the drug in a form which ensures its immediate absorption.

Samples of BISHOP'S CAFFEINE will be sent post free to Medical Men in the United Kingdom by

ALFRED BISHOP, Ltd., 48, Spelman Street, LONDON, E.1.

To prevent substitution, please specify BISHOP'S on prescription.

One of the Glaxo Chemical Laboratories.

Glaxo

The Super-Milk

WE GUARANTEE that all dried milk sold under the trade mark **GLAXO** is made by the Glaxo Process in the Glaxo factories in Australasia. These factories are under our own immediate supervision and management, and the milk is obtained from cows that feed on good green grass, rich in vitamins, all the year round.

Proprietors: Joseph Nathan & Co., Limited, London and New Zealand.

WHAT MAKES GLAXO DIFFERENT. No. 1. of Series.

The Testing of Glaxo

Few, if any, ordinary dried milks are systematically tested. An occasional analysis may be made, but this is insufficient to ensure the highest quality. Constant supervision is essential.

Glaxo is under continuous chemical and bacteriological control from the time the cow is milked until the lid is placed on the tin. The milk is tested when received at the factories, tested when dried, tested again when packed, and these examinations are made daily.

When mixed for use, Glaxo contains less than one-hundredth of the bacteria present in Grade A (Certified) Milk. Thirty gallons of reconstituted Glaxo contain fewer bacteria than one teaspoonful of cow's milk. No other dried milk can offer such definite composition, and unvarying bacterial purity as Glaxo affords.

THOUSANDS WEAR

The Lyndals Shirt

WITH ITS

Perfected Cuff System.

You change your Cuffs as you change your Collar

EVERY MORNING.

The Lyndals Shirt is made to perfection of the highest quality durable smart shirtings, with 3 pairs of detachable reversible cuffs.

The Lyndals Shirt saves unnecessary washing and laundry wear and outlasts two ordinary shirts of equal quality. It quickly saves its cost, and you have the boon of delightfully clean shirt and cuff wear

EVERY DAY.

Detachable, reversible, double Soft Cuff.

Detachable, turnable, Still Cuff.

Prices 8/6, 10/6 and 12/6 Post Free. (SHIRT CUFFS 2/- EXTRA).

Call or write for Patterns and Illustrated Price List. Please state if woollen, silk or cotton patterns required. Enclose 4/- for postage.

A British Medical Association Lecture ON THE REPRODUCTIVE ORGANS IN RELATION TO MENTAL DISORDERS.*

BY
SIR FREDERICK W. MOTT, K.B.E., M.D., LL.D., F.R.S.,
DIRECTOR OF THE PATHOLOGICAL LABORATORY OF THE LONDON
COUNTY COUNCIL MENTAL HOSPITAL, MAUDSLEY HOSPITAL,
DENMARK HILL.

[With Special Plate.]

MR. PRESIDENT AND GENTLEMEN,—Allow me first to thank the East Yorks Division of the British Medical Association for the honour they have done me in asking me to give this address upon the reproductive organs in relation to mental disorders, a subject to which I have recently given much attention. Before proceeding to discuss the facts bearing upon this subject let me call attention to the inherent characters of mind in relation to personality.

The Inherent Characters of Mind.

The furniture of the mind is the memory store of our experiences and the bonds that unite them. The quantity and quality of the furniture of the mind depend firstly upon the inherent germinal raw material begetten with the body and derived from species, sex, race, and ancestry, giving each individual a special predetermined plasticity to receive and store impressions and react to them. This raw material of inheritance upon which psychophysical energy, durability, educability, imagination, temper, emotivity, moral and aesthetic sense—personality, in fact—so largely depend, is inborn. These fundamentals of mind are begetten with the body and predetermine character and conduct, as was clearly proved by Francis Galton's inquiry into the history of similar and dissimilar twins, which proved that dissimilar twins remained dissimilar in mental and bodily characters when brought up in the same environment, while similar twins brought up in different environment remained similar in mental and bodily characters. This is a convincing proof of the fact that the organic basis upon which the quality of the mind depends is begetten with the body. If inborn good qualities are deficient or absent there will be, in spite of favourable environment after birth, intellectual, aesthetic, or moral feeble-mindedness of various forms and gradations. Again, if there be inherited a disproporportion and a lack of harmony and integration of the inherent factors of the raw material upon which mentality is based, an unbalanced mind is likely to develop which will shew itself in various departures in conduct from that of the normal stable individual: it may be in the form of eccentricity, mysticism, fanaticism; or the psychoneuroses—for example, hysteria, neurasthenia, psychasthenia, epilepsy, megrim; or the psychoses (the true insanities)—anemia, confusional or toxic psychoses, dementia praecox, manic depressive or periodic insanity, dementia praecox, and involuntional melancholia, as distinct from acquired organic brain disease, such as general paralysis of the insane.

That this tendency to departure from the normal well-balanced mind is largely a matter of inheritance is shown by the study of family pedigrees for several generations, where many or all of these variations from the normal may generally be found in different members of the ancestral stocks. This neuropathic inheritance is often mingled with a streak of genius, especially of the artistic or aesthetic nature.

Photographs of patients showing different forms of insanity were exhibited, including two pairs of sisters with a marked family history of insanity, who were admitted to asylums in early adolescence suffering with dementia praecox, and who are still living and are over 40 years of age. Prior to the war there were 10,000 of the 20,000 odd inmates of the asylums who had been resident for over ten years and 5,000 over twenty years. A considerable proportion of the chronic cases are these cases of dementia praecox.

Neuropathic and Psychopathic Predisposition in Relation to Psycho-physiological Stress.

The study of relatives in the London County asylums by a card system, and by the method of systematic inquiry and construction of a large number of pedigrees, and the investigation of statistical data relating to the age of onset

of insanity in the offspring of insane parents, afford to my mind conclusive evidence of three facts in relation to the causation of mental disease:

1. The importance of a neuropathic and psychopathic heredity.
2. The special liability of the neuroses and psychoses to occur in adolescence and the involutive periods of both the male and female sexes, when the sexual function matures and wanes.
3. The influence of child-bearing and lactation in women, acting as exciting causes.

That the inborn predisposition is the most important fact in the development of neuroses and psychoses is also shown by the frequency with which these various psychoneuroses and psychoses occur at periods when normal physiological changes occur in the body—for example, adolescence, when the sex instinct is aroused and matured, and the involutive period, when it wanes. Again, in women, pregnancy, parturition, and lactation are normal physiological processes of the sex instinct, yet a number of cases of insanity in women designated puerperal mania or lactation mania occur as a result of a normal physiological process. Even in cases of septic origin predisposition cannot be excluded. For many women have puerperal septicaemia but do not become insane. The term "puerperal mania" is a misnomer in a way, for the cases belong to three groups: (1) Exhaustion psychosis or toxic psychosis, (2) manic depressive insanity, and (3) dementia praecox.

1. The greater influence of the extrinsic cause, especially if it be pathological—for example, toxic conditions—the more probable is the recovery by treatment removing the source of the sepsis, and less the liability to a recurrence.

2. Emotional shock, worry, anxiety, insomnia, and exhaustion are also regarded as important exciting factors. But the war has shown that these are not of such primary importance as was suspected, for it was observed that there was no great increase of insanity among the women in Galicia and East Prussia when they had to flee on account of the invasion by the Russians in the great war. Moreover, Bonhöffer found only five insane among 10,000 Serbian prisoners who had been subjected to every form of stress of war and disease.

If "E" (Fig. 1) represents mental and bodily extrinsic factors, and "I" inborn predisposition, the more of "E" that we can find as a causal factor the more favourable is the prognosis.

FIG. 1.

Statistical Data Relating to Inheritance and Insanity in the Periods of Adolescence and Involution.

The importance of these physiological states of adolescence and involution in the incidence of the onset of insanity is shown by two graphs (Figs. 2 and 3), based upon an investigation of the age at the time of first attack in 503 pairs of parents and offspring, from records of 454 insane parents of 500 insane offspring.

These curves in the offspring show 47.8 per cent. of 500 offspring who became insane in adolescence at or before the age of 25. The 47.8 per cent. of cases of adolescent insanity may be divided into four groups:

1. Exhaustion psychosis, confusional insanity, or dementia, who were discharged recovered.
2. Recurrent insanity—manic depressive—discharged but readmitted on one or more occasions; as a rule the length of the period of asylum detention increases upon each attack, some cases finally passing on to dementia and detention till death.
3. Primary dementia of adolescence or dementia praecox. In the vast majority of cases progressive and permanent detention till death; these cases make up a large proportion of the chronic lunatics in asylums.
4. The imbeciles are relatively few in number, as they are sent to the asylums of the Metropolitan Asylums Board. A few are admitted to the London asylums on account of the onset of acute symptoms. There are also a few cases of juvenile general paralysis, but the great bulk of the cases belong to 1, 2, and 3, and especially 3.

These statistical data were prepared in 1911.

In 1917 I made a further analysis of relative cards since 1911, a period of six years. This analysis was limited to

* Delivered to the East Yorks Division of the British Medical Association on February 10th, 1922.

insane parents of offspring, of which a diagnosis of dementia praecox was made, and instead of 47.8 per cent. there were 75 per cent. of the 69 cases diagnosed as dementia praecox admitted at the age of 25 or under (Fig. 4). Seeing that a great many of these cases were either insane before certification, or by their conduct had given prodromal evidence of oncoming dementia, it is highly probable that all the cases really commenced in the adolescent period.

Prior to the war the two sexes were about equally represented in the admissions. During the war the male cases of dementia praecox were diminished by one-half. This may easily be accounted for by the fact that a number were conscripted in the undiagnosed early stages of the disease, or the disease developed after their admission to the army. It was found that 14 per cent. of the total insane who had served in the army were cases of dementia praecox, which proves the truth

of the assumption I have made in respect to the great fall in the admissions on the male side during the war.

A comparison of the two curves of the parents shows a notable difference. The curve of the fathers does not commence to rise till after 25, and the 30-40 peak corresponds with the incidence of general paralysis of the insane (Fig. 2). It may here be remarked that males suffering with general paralysis are four to five times as numerous in the asylums as females, but this does not account for the main difference in the curves of fathers and mothers. This is due to the incidence of child-bearing and lactation, which causes a steady continuous rise to the climacterium in the maternal curve (Fig. 3). The 50-60 peak corresponds to the involutive period.

It was also computed that only 7.9 per cent. of the children were born after the first attack of insanity in the parent.

Recurrent Insanity in Women and Child-birth.

An analysis of 642 female admissions to three London County Council asylums during the year 1911 showed 148 recurrent cases, of whom 32 (21 per cent.) had children between their respective dates of admission. The inference that can be drawn is, that rather less than one-fifth of the recurrent cases have children after their first attack of insanity. This may be explained by the adoption of contraceptive methods, but my investigations suggest another important cause, namely, early involutional changes in the ovaries in all

Two Schools of Thought in Relation to Dementia Praecox: the Psychogenic and Physiogenic.

There are two schools of thought—one physiogenic, the other psychogenic; the former attributes the mental disorder to a bodily pathological condition, the latter to a non-adaptable psychological function. The frequency with

which psychoses and psychoneuroses follow emotional shock connected with the sex impulse, the character of the dreams and their interpretations, the nature of the hallucinations and delusions in a great number of the cases suggest an origin in excitement or repression of the sex instinct.

Because by the aid of the microscope we cannot show an organic cause in epilepsy, neurasthenia, or hysteria, and other psychoneuroses, it does not follow that the deranged mental function is not due to deranged bodily function. It was thought, and is still, by the psycho-analyst

FIG. 3.

FIG. 2.

school that in the primary dementia of adolescence—dementia praecox, as it is called—there were no bodily changes sufficient to account for the signs and symptoms of mental disease. The physiogenic changes that are met with it is stated by Jung, are the result, not the cause, of the psychogenic disorder. Thus this author in his work *Analytical Psychology* states:

"The difference between us is as to the question whether, in relation to anatomical basis, the psychological disorders should be regarded as primary or secondary. The resolution of this weighty question depends upon the general problem as to whether the prevailing dogma in psychiatry—'disorders of the mind are disorders of the brain'—presents a final truth or not. This dogma leads to absolute sterility as soon as universal validity is ascribed to it."

And—

"Such an idea is only incomprehensible to those who smuggle materialistic preconceptions into their scientific theories. This question does not even rest upon some fundamental and arbitrary spiritualism, but upon the following simple reflection. Instead of assuming that some hereditary disposition, or a toxæmia, gives rise directly to organic processes of disease, I incline to the view that upon the basis of predisposition, whose nature is at present unknown to us, there arises a non-adaptable psychological function which can proceed to develop into manifest mental

Fig. 4.—Broken line=ages of parents upon first attack of insanity. Uninterrupted line=ages of offspring upon admission to asylums.

disorder; this may secondarily determine organic degeneration with its own train of symptoms. In favour of this conception is the fact that we have no proof of the primary nature of the organic disorder, but overwhelming proofs exist of a primary psychological fault in function, whose history can be traced back to the patient's childhood."

But when doctors speak of psychogenic, what do they mean? The furniture of the mind is made up of past

experiences and the bonds that unite them, but there can be no mind without memory, and there can be no memory without body. All psychical processes are subordinate to physiological processes, and all physiological processes are associated with, and dependent upon, oxidation processes. That the mind reacts on the body and the body on the mind is certain, and that the bodily symptoms of many functional neuroses, such as hysteria and anxiety neurosis, can be cured by suggestion and persuasion is certain. In the former of these conditions we have a perseveration of an idea, brought about by auto-suggestion or hetero-suggestion; in the case of the conscript it was an unconscious defence mechanism connected with the instinct of self-preservation; in civil life it is connected with the sex instinct in the majority of instances. The anxiety neuroses are, in a number of instances, dependent upon a wound of the *amour-propre*.

Time, however, will not permit me to do more than refer to the psychoneuroses, and I shall devote my attention to mental diseases which may be directly associated with the function of reproduction.

The Insanity of Adolescence.

The insanity of adolescence was first described by Clouston, who recognized two types—a curable, and an incurable which went on to progressive dementia. To this latter type was given the name "dementia praecox" by Kraepelin, who divided it into three clinical groups: the katatonic, the hebephrenic, and paranoid. Whether such a classification is justifiable or not on these lines is open to question; it is certainly of less value to know what a thing is called than to know what it is, and to find out how it has come about that an individual's mind is deranged. This can only be effected by careful investigation to ascertain what an individual was born with and what happened after birth, and in this respect psychological inquiry to ascertain the development of the mind is as necessary as to know the development of the body. It may be, as Jung says, that a primary psychological fault in function, whose history can be traced back to childhood, will be found in most of these patients. This fault, he would say, is a predisposition of which we know nothing. I would urge that there is evidence to show that, at any rate in dementia praecox, there is an inborn genetic lack of durability and reproductive formative activity. Kraepelin discusses and discards the idea that this disease is due to masturbation, and does not, as Clouston did, recognize a "masturbational insanity." Onanism, according to Kraepelin, is a symptom; but it may be a contributory cause of the mental disorder. Most psychiatrists recognize the association of the disease with the sexual functions. Kraepelin, Urstein, and other authorities suggest toxins from the sex glands as a probable cause of the mental disease.

Morbid Histological Changes in the Brain.

Most psychiatrists accept the findings of Nissl, Alzheimer, and those who have followed them in associating the mental symptoms with the microscopic changes in the ganglion cells of the cortex, mainly affecting the nucleus and causing thereby a defective metabolism and function of the ganglion cells with pigmentary or lipoidal degeneration, akin to that met with as a result of senile change.^{*} Jung, as we have seen, takes an entirely different view of this question.

The Physiogenic Explanation of the Vital Impulse in Relation to Mental Disorders.

I have endeavored by my researches to show that the mental breakdown in adolescence, in the puerperal and lactational states in women, and in the involutive period in both the male and female sexes, is due to a failure of the vital impulse (*élan vital*) or libido of the psycho-analysts. But this vital impulse is an inborn character, and, like longevity and durability, it is due to bodily conditions. Up to puberty, this vital impulse is manifested in the psycho-physical reactions for self-preservation by nutrition for the growth of the body and for its defence against injury. But Nature is unmindful of the individual, mindful only of the species, and the body is, after all, but the vehicle for the germ cells, so that all the vital energy over and above that which is necessary for the functional activities of the somatic tissues is in adolescence available as psycho-physical energy for the formative productive energy required for reproduction. In adolescence a complete mental revolution occurs peculiar to each sex, and the vital impulse is now directed mainly towards

the fulfilment of the instinct of propagation, as well as, and even more than, self-preservation. The vital impulse to psycho-physical activities is manifested in new emotions, passions, and sentiments, and the reactions are peculiar to each sex. If these sex activities are not frustrated and repressed, which so often happens, owing to the taboo of society, and the disharmony which exists between physiological sex relations and social customs, usages, and traditions, the sex impulse to propagate is accompanied by a *joie de vivre*, "a new and unaccustomed spirit," au *élan vital*, so admirably expressed by Shakespeare in *Romeo and Juliet*:

"My bosom's lord sits lightly on his throne;
And all this day an unaccustomed spirit
Lifts me above the ground with cheerful thoughts."

Now what will happen if there should be a suspension or suppression of this libido or vital (love) impulse due to an inherent potential deficiency or owing to physiological stress or pathological conditions? In what structures of the body should we expect to find evidence of functional organic deficiency? We should expect to find a deficiency of organization in the germ cells, for it is by them that the vital energy is genetically transmitted. This energy, characteristic of every living organism, to build itself up according to a certain inherited type or pattern, is embodied in the nuclear substance of the fertilized ovum derived from the male and female gametes, in virtue of which it can turn to account both the food and the force which it derives from without. The productive energy, which in the normal male is manifested by an almost unlimited nuclear formative spermatogenic activity for more than two-thirds of a man's life, and in the normal female by a fertility and capacity of bearing and nourishing offspring, the mother remaining in good mental and bodily health during the reproductive period, denotes an inborn endowment of formative vital energy.

It follows that evidence of a primary regressive atrophy of the spermatogenic functions, and of a regressive atrophy and failure of the primordial follicles of the ovary to develop Graafian follicles, is indicative of an hereditary deficiency of the genetic vital impulse. Now I have shown in a large number of cases of dementia praecox, in both the male and female sexes, that a primary regressive atrophy of the reproductive organs occurs. In the female the disease is often manifested after the birth of the first child. Thus the woman suffers with puerperal mania which terminates in dementia, from which the patient never recovers, although she may with care live a vegetative existence for a number of years in an asylum. Can anything more tragic happen to a young husband than this? Yet I have investigated not a few such cases of puerperal mania, terminating in dementia praecox, affecting a young married woman after the first confinement. Some few of the cases occurred in unmarried women, sometimes of the imbecile type. Emotional shock and social degradation may in such cases act as exciting factors in the production of the mania. In these cases of post-puerperal dementia I have found in the ovary macroscopic and microscopic evidence of failure of reproductive power. The organs are small, shrivelled, and densely fibrous, showing no Graafian follicles, a totally different appearance from the ovaries of a young woman dying of acquired organic brain disease—for example, general paralysis of the insane. Microscopic examination shows a few old corpora albicantia or corpora lutea, but no recent follicle formation; the primordial follicles are greatly diminished in numbers and are seen in all stages of degeneration and replacement by the fibrous stroma. Examination of the nucleus (germinal vesicle and germinal spot) of the ovum shows a deficiency in the chromatin substance, consequently indicating a failure of the productive vital energy necessary to stimulate the development of the zona granulosa cells and formation of the Graafian follicles. This nuclear defect in the female germ cell has been said to be due to the effects of chronic disease—for example, tuberculosis, from which so many of these patients die; but we know that tuberculous women are not infertile and do not develop mental symptoms—indeed, the tuberculous woman while pregnant seems to put forth a supreme effort of the body to resist the disease, and thereby enables the child to develop and be born alive, afterwards to be followed by a "rapid decline" and frequently death of the mother, which to my mind affords a proof that every cell of the body has an organized impress—or, if you like, a pre-organized mne—*mne*—that its great mission is the preservation of the species. A more direct argument, however,

*Lantern slides were shown illustrating these changes, for a full account of which the reader is referred to "Studies in the Pathology of Dementia Praecox."

* Used in the broad sense of Jung.

against chronic disease being the cause of the ovarian regressive atrophy is that occasionally I have had a case of dementia praecox in a female who was in good bodily health, and died of acute disease after a few days' illness. I have found the same atrophic changes and fibrotic substitution as in the cases dying of chronic disease. In the ovaries of a general paralytic woman, dying before the involutive period of life is reached, although she may have suffered with chronic disease for years before death, yet we shall find evidence, especially if she is a married woman, of numbers of corpora albicantia and of corpora lutea, a history of having had a number of children, in some instances miscarriages or abortions, or children born dead—the result of the syphilis. The evidence of an inborn germinal defect is, in the greater number of cases, absent in general paralysis. There is no primary regressive atrophy of the ovaries. In spite of the mental and bodily disease from which she suffered, the ovaries usually show follicles undergoing development in all stages; most of them, however, become atretic. In the dementia praecox cases there is usually no sign of atretic follicles, although there are old corpora atretica (see Plate, Fig. C, 1, 2, 3, 4).

Dr. Iris Fox has been good enough to abstract the notes of my observations upon a large number of ovaries in various forms of insanity. The conclusions are highly suggestive of the fact that all forms of insanity are associated with a tendency to failure of reproductive power and early involution, yet we know that chronic disease will produce the same effects. Still there can be no doubt that dementia praecox, an inborn disease, shows this loss of reproductive power to a far greater degree than general paralysis of the insane, an acquired disease, which accords entirely with my observations on the testes in these two diseases.

Summary of Results from Examination of Clinical and Pathological Data of 97 Cases of Patients under 50 Dying in Asylums and of 8 Dying in Hospital.

I.

(a) Diminished follicles occur in most types of mental disease and in many controls. The details suggest that this diminution may be a more constant feature of dementia praecox than of the other forms of insanity.

(b) Sclerosis (which has been assumed to be absent when not noted) is also common, but is remarked in a much higher proportion of the dementia praecox cases than in any other disease.

(c) Vascular thickening may accompany sclerosis, or occur independently (for example, in general paralysis of the insane).

II.

Degeneration of follicles is found in a very high proportion of all the ovaries examined. No deduction can therefore be drawn from it here.

III.

The nuclear condition of ovum has been noted in 44 cases. The figures show a high proportion of cases of nuclear degeneration in dementia praecox. The other figures are too small to suggest a special freedom from nuclear degeneration, but suggest a special freedom from nuclear chromatin in general paralysis. With regard to other mental diseases there is no evidence here to show that they differ in this respect from dementia praecox. The figures suggest that the nuclear degeneration is probably unrelated to circulating differences, since the general paralysis of the insane cases show a fair number with vascular degeneration. The figures, however, are too small to establish this point.

IV.

(a) Some degree of maturation of the follicles is present in the great majority of cases, the exceptions being almost always cases of dementia praecox, or (?) dementia praecox.

(b) No clear deductions seem possible from either the corpus luteum content or the menstrual history—from the former because the type of corpus luteum is not generally noted, and, if it were, its dating would be somewhat empirical; from the latter because of the possible inaccuracy of the record.

(c) Shows a connexion between the duration of the disease and ovarian change as a rule. But this does not establish any special relationship beyond that existing between other chronic and acute diseases and ovarian function.

I am at present pursuing the investigation by an intensive study of the ovaries and endocrine glands in a number of

cases in which adequate clinical data have been obtained. So far as the investigation has proceeded, regressive atrophy of the ovarian functions is a marked feature of dementia praecox.

Now if we turn to the male adolescent who develops dementia praecox—and I have investigated now the testes in thirty fatal cases, and in many of these the brain and endocrine glands—we find evidence of a primary regressive atrophy. The first account of these investigations was published in the *BRITISH MEDICAL JOURNAL*, vol. ii, 1919, pp. 655, 698, 737, under the title "Normal and Morbid Conditions of the Testes from Birth to Old Age in 100 Asylum and Hospital Cases," and in *Studies in the Pathology of Dementia*, of the Royal Society of Medicine, vol. . . . of Psychiatry; "The Psycho-pathology of Puberty and Adolescence," Morison Lectures, 1921; "Second Maudsley Lecture"; published in the *Journal of Mental Science*, July, 1921.

I will briefly summarize the results of these investigations together with the results of a further investigation on dementia praecox and other psychoses, especially in relation to the interstitial cells of Leydig, which is now in the press and will be published in the next number of the *Proceedings* of the Royal Society of Medicine. There is, generally speaking, a correspondence between the degree of regressive atrophy of the testes and the duration of the mental symptoms. The atrophic process may result in all stages of failure of nuclear formative activity of the spermatogenic epithelium terminating in a complete

disappearance, leaving only the Sertoli cells. There are also profound nuclear and cytoplasm changes in the interstitial hormone cells. This primary atrophy resembles the changes met with in the testes of cases of involutional melancholia, post-adolescent dementia praecox, and terminal dementia and manic depressive insanity. Besides the failure of spermatogenesis, there is pigmentary degeneration of the interstitial cells in 25 per cent. of the cases of dementia praecox dying in adolescence, a sign of senile decay. This regressive atrophy was not found as a rule in general paralysis and other forms of organic brain disease. These investigations appear to show that in the male and female suffering with these various psychoses there is a failure of the vital formative impulse of reproduction, especially marked in cases presenting the clinical signs and symptoms of dementia praecox. Lantern slides were exhibited in illustration of these facts, and the reader is recommended to consult the communications referred to for further precise and detailed information.

In conclusion, it may be noted that these observations on regressive atrophy of the male reproductive organs have been confirmed by the researches of Tiffany.

THE Medical Faculty of Vienna has issued a programme of a special post-graduate course beginning on June 19th. The course is in medicine and the diseases of children, and will have special reference to treatment. There will be two sessions on each day—in the morning from 8 to 11 and in the afternoon from 3 to 6. The course will be conducted by the professors, privatdozenten, and assistants in the medical faculty; it will consist of lectures, clinical demonstrations, and demonstrations in the pathological laboratory, and will range over a wide field. The last day, Saturday, July 1st, will be chiefly occupied by a visit to the neurological and psychiatric clinic. The registration fee for foreigners is 10,000 kronen. A supplementary course on radiology will be given in the following week; it will begin on Monday, July 3rd, and end on July 9th, when a visit will be paid to the special lupus institution in Vienna. The fee to be paid by foreigners will be 100,000 kronen. Full particulars of both courses can be obtained from Dr. A. Kronfeld, Porzellan-gasse 22, Wien; the Editor of the *BRITISH MEDICAL JOURNAL* has a few copies of the programme; one will be sent to applicants on receipt of postage.

DESCRIPTION OF SPECIAL PLATE.

FIG. A.—Ovary of G.: dementia praecox. Age at first attack, 25; pregnant seven months; died eighteen months later. Weight of ovaries, 3 grams and 2 grams. Old corpora lutea vera; thickened vessels indicative of involutional change; no maturing Graafian follicles; one small degenerated immature follicle on the surface; very few primordial follicles left (Fig. C). (Magnification 10 × 1.)

FIG. B.—Portion of cortex of ovary, showing complete absence of follicles—sclerosed fibrous irregular surface with dense stroma beneath. (Magnification 100 × 1.)

FIG. C.—Four primordial follicles. These were in a group and show: (1) Lining epithelial cells intact containing ovum with oval swollen nucleus; the epithelial cells of the zona granulosa have already separated from the theca interna, a sign that further maturation will not proceed. (2) Lining epithelium degenerated. (3) The same more marked. (4) Commencing ingrowth of stroma. This group was the best that could be found. (Magnification 800 × 1.)

patient on admission to hospital.

THE ETIOLOGY OF PRIMARY CATARACT.

BY

HENRY KIRKPATRICK, M.B.,
LIEUT.-COLONEL I.M.S. (RET.).

DESPITE the fact that primary cataract has a strong personal interest for so many of us, its causes have been, and still are, veiled in a mist of uncertainty which all our efforts have failed to pierce and which even now shows little signs of lifting. Nevertheless, it may prove profitable to review our knowledge of the subject and to consider it in the light of discoveries made in other branches of medicine. So long as we remain in ignorance of the causes of the disease we shall be unable to prevent its occurrence or to bring it to a standstill once it has commenced to develop, and the treatment is likely to remain, as hitherto, mainly surgical.

It is not proposed to consider here forms of cataract caused by purely local conditions, such as those varieties which follow trauma, detached retina, intraocular tumours, retino-choroiditis, and inflammatory exudations on the lens capsule, or such as are due to developmental defects in the lens vesicle, but only those progressive and non-progressive forms which may be considered to be primary in nature.

Amid the general obscurity certain known facts stand out clearly. These are:

1. A cataract is the result of a degeneration of the fibres or cells of the lens.

This degeneration may be due to a cause which is active for a limited period only. In this case the cataract is likely to be non-progressive—for example, punctate cataract, lamellar cataract, etc. In the case of a non-progressive cataract the opacity resulting from the degeneration becomes buried in the substance of the lens by the subsequent growth of healthy fibres around it. The cause may, on the other hand, be one the action of which is continued; a progressive type of cataract—such as senile or presenile—is then produced. It is likely that, if a large portion of the lens fibres have degenerated, the degenerative process may continue, even though the primary causes have ceased to be active.

2. Primary cataract is nearly always bilateral.

This indicates that the cause of the disease must be sought for in some constitutional and general change or defect. The cataract may grow more rapidly and may be more advanced in one eye than in the other, but it is exceedingly rare to find the occurrence of uncomplicated primary cataract limited to one eye. When the cataract is further advanced in one eye than the other it will often be found that the more affected eye is the subject of an uncorrected error of refraction of long standing. In some cases it will be found that a correcting lens has been worn in a faulty position. An eye which is the subject of an uncorrected error of refraction and strain appears to be specially liable to the ocular complications of diabetes, nephritis, syphilis, and focal sepsis; it is natural, therefore, to expect that such an eye may be exceptionally susceptible to cataract formation should a constitutional cause of the disease be present. Asthenopia, due to refraction error, is occasionally associated with a bubble-like opacity situated in the anterior cortex very close to the capsule. When examined with an electric ophthalmoscope, in the aperture of which a plus 12 D lens has been placed, the opacity is found closely to resemble a bubble of gas seen at the bottom or on the sides of a tumbler containing soda-water. These opacities may, on rare occasions, disappear after the error has been corrected.

3. Certain conditions are generally admitted to predispose to the development of cataract.

Senility, diabetes, pellagra, the ingestion of certain poisons, and rickets are the most prominent of such conditions; but cholera, gastro-intestinal disturbances, focal infections, and debilitating general conditions are considered by many to be factors in the causation of cataract.

4. An hereditary predisposition to the disease exists.

The lens cells of some persons, therefore, suffer from an inherited susceptibility to certain noxious influences, or the organs and tissues of their bodies inherit a defect which allows disturbances in their function to occur with unusual facility; such disturbances, injuriously affect the nutrition of the lens fibres.

5. Convulsions of the type found in tetany have frequently been followed by the development of cataract.

The observations of Noël Paton and Findlay suggest that tetany is due to a defective action of the parathyroid glands; these ordinarily detoxicate a guanidine compound derived from muscular metabolism; tetany occurs if this process is interfered with. Fischer and Triebenstein claim to have found evidences of tetany and latent tetany in 88.2 per cent. of cases of senile and presenile cataract, whereas such evidences were only found in 8.3 per cent. of control cases free from cataract.

6. Cataract has been observed to follow the removal of the thyroid, either for experimental purposes or for surgical reasons: Thyroidectomy is not, however, always followed by cataract, and, assuming the operation to be complete, some additional factor must be present to cause the disease in such cases. In this connexion it must be remembered that it may be difficult to avoid injury to or removal of the parathyroids in the execution of a thyroidectomy. The writer has seen cases of cataract associated with hypothyroidism, the history and course of which strongly suggested that the ocular condition was dependent upon deficient endocrine function.

7. Excessive glare may be a contributing cause of cataract.

A peculiar form of slowly progressive cataract is found amongst bottle-makers and furnace workers. Its frequent occurrence among such workers suggests that the rays which emanate from a furnace may, in some cases, be capable of inducing a degeneration of the lens fibres; the fact that they do not invariably do so suggests that additional factors, possibly of a constitutional nature, may be present in those workers who become affected by the disease. Exposure to excessive heat and glare may also be one of the reasons why cataract occurs with such frequency amongst natives of India. The disease, however, does not appear to be unusually common amongst well-nourished Europeans of middle age who are resident in the country, so that such exposure is probably no more than a minor cause of cataract. It is of interest to note in connexion with this subject that Elliot states that he has met with a proportion of cataract amongst retired Anglo-Indians, which strongly suggests that residence in the East influences the liability to the disease. It has been stated that the opacities of commencing cataract are most commonly found in the lower part of the lens, and it has been suggested that this is due to the fact that the bulk of light rays come from above and, falling upon the lower portion of the lens, affect it injuriously. The writer is not at all convinced by his experience in India that, in that country at all events, the lower portion of the lens is much more frequently attacked by early cataract than other areas. Elliot has pointed out, however, that a great part of the light entering the eye in the tropics is reflected chiefly from the ground, and that the eyes are often protected by a solar topi or turban from the light which comes from above. In the tropics, therefore, one would expect to find that injurious rays affect the upper part of the lens at least as commonly as the lower.

8. Cataract occurs more commonly in India than in most other countries.

After making due allowance for the fact that the proportion of competent surgeons to the size of the population is small, the vast numbers of cases of cataract dealt with by individual surgeons in India leads one to the irresistible conclusion that the disease is extraordinarily common in that country. The great number of persons, blind from cataract, met with on the roads and streets is confirmatory evidence. All classes of the native population appear to be affected, but the disease seems to be more prevalent among the poorly fed lower classes than among the well-to-do. Cataract also seems to be most common in the hotter, drier, and more arid districts.

The differences between the Indian and the European, which bear on the subject, may be divided into three groups: (a) constitutional; (b) dietetic; (c) general surroundings.

(a) *Constitutional*.—The average Indian matures at an earlier age than the average European and, as a rule, he pays the penalty for this by an earlier occurrence of the retrogressive tissue changes due to senility; these changes are shown in the lens by a comparatively early appearance of presbyopia and by the fact that the accommodative power of a

middle-aged Indian is rarely equal to that of a European of the same age. Gastro-intestinal troubles afflict most residents in the tropics, whether Indian or European, but the European is usually in a better position to deal with these than the Indian is. Helminthiasis is extraordinarily common amongst Indians: at least 70 per cent. of the general population in the south of India suffer from hookworm disease.

The prevalence of pyorrhoea, in a very advanced degree, amongst better class Indians is a most striking feature in the south of India, and probably in other parts of the country too. The disease is very common among the lower classes also, but these do not appear to be so generally affected as those who are more wealthy. The soft nature of the diet, the habit of betel chewing, and a fondness for sweets seem important factors in the causation of the condition.

A large number of Indians suffer from diabetes. The disease appears specially to affect those of the well-to-do and upper classes, and it is interesting to note that it sometimes has an undoubted connexion with pyorrhoea. The writer frequently found that the urine of a patient suffering from glycosuria rapidly became free from sugar when his pyorrhoeic teeth had been extracted and he had been rendered free from oral sepsis. Patients have often told him that they had formerly suffered from glycosuria, but that they were then free from the disease. Such patients were found on examination to be edentulous, the pyorrhoea from which they used to suffer having undergone a natural cure. A large proportion of Indian patients operated upon for cataract in private practice suffered from glycosuria.

(b) *Dietetic*.—The diet of Indians varies greatly in different parts of the peninsula, and is also influenced by circumstances of caste and religion. Despite these differences, the fact that the bulk of the diet is composed of a dry grain is a feature common to all. A lack of fresh vegetables exists in the diet of most Indians, especially those of the lower classes. During many months of the year fresh vegetables are only obtained with difficulty in the more arid parts of the country—even by the well-to-do. The dietary of Indians is consequently poor in essential food factors, and this deficiency is accentuated by the probable paucity of such substances in the vegetables, etc., grown in the hot season. McCarrison has found that the milk of cows fed upon dry fodder lacks essential factors which the milk of cows fed upon fresh green stuffs contains; long-continued hot, dry weather is thus likely to exert some influence upon the occurrence of diet deficiencies. His observations also show that the endocrine glands are injuriously affected by a deficiency of vitamins in the food, and that the harmful effect is likely to be enhanced if the diet is badly balanced and contains an excess of carbohydrates. This lack of essential food factors is frequently shown in India by the occurrence of beri-beri, scorbutic conditions, and keratomalacia.

(c) *General Surroundings*.—Exposure to heat and glare and a life passed in bad hygienic surroundings are the characteristics of the general conditions under which most Indians live. As stated above, exposure to glare may have some influence upon the causation of the lens degeneration from which they so often suffer, but other additional factors are likely to be required to produce cataract. Bad hygienic surroundings may sometimes cause constitutional conditions which favour the occurrence of cataract, but their influence in this connexion is probably slight. The tropical sun is a powerful ally of the sanitary officer in the rural districts, and, owing to its influence, many villagers escape punishment for their hygienic errors.

It has been suggested that the sclerosis of the lens fibres, which normally occurs with advancing age, is the cause of cataract. Magnus considered that the resistance to the flow of nutritive fluid, offered by the sclerosis of the nucleus, was an important factor, and Becker supposed that an unequal and irregular sclerosis produced a stress and strain upon the cortical fibres which led to the formation of clefts and spaces between them. When considering the consequences of sclerosis it must be remembered, however, that although opacities are present in the lenses of very many people who are advanced in years, yet the proportion of old people affected by progressive cataract is not very high. Obviously, since sclerosis of the lens almost invariably occurs with the advance of age, and progressive cataract does not do so, this hardening of the lens cannot be considered to be the chief cause of senile cataract. Sclerosis of the lens cannot account for those cases of presenile cataract which occur at an age when the hardening of the nucleus is negligible. In discussing the causes of primary cataract it is important to consider all

forms of the disease together, and to avoid concentrating the attention upon one particular variety.

The lens epithelium, owing to its ectodermic origin, might be expected to react injuriously to influences towards which allied ectodermic structures display a special susceptibility. Some evidence exists that this occasionally occurs in the case of conditions associated with a deficiency of thyroid secretion; but, when one remembers that the lens is a purely passive structure, and that the nutritive requirements of its fibres are very limited, one would expect its response to noxious influences to be small and tardy. The difficulty of tracing the cause of a cataract in any particular instance is considerably enhanced by this fact.

A consideration of the conditions which are generally admitted to predispose to cataract shows that most, if not all, are such as are likely to be accompanied by marked disturbances of the endocrine organs. Senility is, perhaps, the condition which is most often associated with cataract. Failure of the generative glands to function fully is a leading feature of senility, and, owing to the delicate balance that exists between the activities of the internal secretory organs, such failure must require a compensatory effort on the part of the other endocrine glands. Satisfactory compensation occurs in most cases, but its establishment may sometimes be rendered difficult, or may be prevented by the existence of other factors, such as infections, food deficiencies, and hereditary influences.

Diabetes is generally recognized to be associated with a disturbance of the endocrine organs, and it is possible that such a disturbance may be a more powerful factor in the production of a diabetic cataract than the presence of a minute quantity of sugar in the aqueous humour. This latter may, however, be a contributing cause of the lens degeneration. Pellagra is a disease considered by many to be due to a food deficiency. Considerable disturbance of endocrine function occurs in it, and symptoms of hypoparathyroidism, such as "Chvostek's sign" (mechanical irritability of the facial nerve) and brittleness of the nails, are common.

Gastro-intestinal disturbances, infections, and the food deficiencies and conditions of malnutrition so common in India, are also causes of defective endocrine function, and may in this way affect injuriously the nutrition of the lens and render its fibres liable to degeneration.

It has been suggested by Peters that the cataract which follows tetany may be due to an irregularity in the supply of lymph, caused by a cramp of the ciliary muscle during the fits; tetany, however, is a manifestation of defective endocrine function—in this instance of the parathyroid—and it is possible that the cataract may be caused by a defect in the quality of the lymph rather than by a defect in its quantity. In any case the number of cataracts, the cause of which can be ascribed to convulsions, is by no means great and only represents a very small proportion of the primary cataracts met with; it is quite possible, however, that minor degrees of parathyroid deficiency, insufficient to cause convulsions, may be comparatively common, and that such may have an important influence in causing the disease.

It will thus be seen that a fair amount of evidence exists which suggests that a defective function of the endocrine organs may be one of the essential causes of primary cataract. From clinical observation, and from the known effect of thyroid and parathyroid deficiencies upon tissues allied to the lens, it might be expected that disturbances in the function of these glands would most likely prove determining factors; such disturbances, however, need not necessarily occur primarily in these glands, but may be dependent upon a failure in the function of other endocrine organs.

Whilst it must be admitted that it is not possible to state with certainty the cause of primary cataract, the following conclusions appear to be legitimate:

1. The cause of primary cataract is probably a constitutional one.
2. Most of the morbid conditions which are associated with the development of primary cataract injuriously affect the action of the endocrine glands.
3. Primary cataracts sometimes follow thyroid and parathyroid deficiencies, and are almost certainly then caused by a disturbance of endocrine function.
4. Exposure to injurious heat and light rays and the existence of an uncorrected error of refraction are likely to determine the formation of a cataract in the eye of a person who is predisposed to a degenerative change in his lens fibres by a constitutional defect.

PNEUMONIA NEONATORUM.*

BY

FRANCIS J. BROWNE, M.D., CH.B. ABERD.,

F.R.C.S. EDIN.,

RESEARCH PATHOLOGIST, ROYAL MATERNITY HOSPITAL, EDINBURGH.

(Working under the Medical Research Council.)

OUT of the 80 cases of infantile death there were 21, or 26.25 per cent., in which the cause of death was found to be pneumonia.

Eleven of these occurred in premature and 9 in full-time infants, the ages varying from 8 hours to 5 weeks. The very large proportion occurring in premature infants is to be noted, and illustrates the increased liability to infection on the part of the premature infant. Thus, if we take the proportion of premature to full-time infants as 1 to 10, we arrive at the conclusion that the premature infant is about fourteen times as liable to die from pneumonia as the infant born at full time.

Associated Conditions.—Five of the infants were syphilitic, another was probably so, while another had fracture of the supraorbital plates with extradural haemorrhage overlying them. One of the syphilitic cases showed an extradural haemorrhage in the spinal cord. In many of the cases, especially amongst the premature infants, there were atelectatic areas in the lungs, and in some cases these involved part of one lung and a large part of the other. It is, therefore, probable that atelectasis is a predisposing factor in the causation of pneumonia.

Premature Rupture of Membranes and Pneumonia.

A consideration of some of the cases would seem to show that premature rupture of the membranes can allow ante-natal infection to occur, and that a child may be born not only infected, but even suffering from pneumonia in an advanced stage.

In one case the mother was admitted to hospital after a long delay at the patient's home. The membranes had been ruptured for some time before admission. Forceps were applied in hospital and a blue baby, breathing badly, was born, which died eight hours afterwards.

At post-mortem examination the child was found to be at full time and 3,800 grams in weight. The lower lobes of both lungs were of solid consistence, and on squeezing the cut surfaces they exuded a yellowish frothy fluid. The lower lobe of the right lung sank in water, and each pleural cavity contained about two ounces of thin blood-stained serum. Microscopically the lungs showed an advanced degree of catarrhal pneumonia in the stage of grey hepatization. Granular debris was the main content of the alveoli, but some pigment-containing endothelial cells, a few polymorphs, lymphocytes, and an occasional disintegrating red cell with some fibrin could still be made out. At other parts no cells whatever could be found, and the whole appeared to be a necrotic mass, in which even the alveolar walls could scarcely be distinguished.

Cultures from the lung on blood agar yielded an organism of the pneumo-bacillus group. It is impossible that such an advanced degree of grey hepatization could have been reached in the eight hours during which the child lived, and its blueness and difficulty in breathing at birth are strong evidence in support of ante-natal pneumonia.

A second case was a four para with contracted pelvis. The first two children had been born dead at full time (craniotomy). The third labour was induced, and the child is alive and well. The present labour was also induced by packing the lower uterine segment with gauze; the packing was removed in twenty-four hours, when the membranes were found ruptured. Labour pains did not start, however, for three days, during which the patient received hot douches. Labour was in the end rapid, the child being "shot out." It required resuscitation, and breathing was wheezy and rapid: It lived three days, and during this time it was blue, its breathing difficult, and the abdomen distended.

At post-mortem examination the weight was 2,690 grams, length 20 inches, and therefore it was very near, or actually at, full time. The cord was dry and healthy. In the right pleural cavity there was about an ounce of brownish-yellow purulent fluid containing flakes of lymph. The right lung was quite solid except for a small part at the apex. On section it resembled grey marble, greyish and reddish-brown areas alternating, and on squeezing it exuded a brownish purulent fluid. The left lung was crepitant and oedematous, and at its lower margin there were a few well-defined abscesses 1 mm. in diameter. The heart showed marked dilatation of the right auricle and ventricle. The tricuspid valves were puckered and covered with vegetations and dark-coloured blood clot. The mitral valve presented a similar appearance, but less marked, while the aortic and pulmonary valves seemed normal. Microscopically the lungs showed typical grey hepatization with large areas of necrosis, and the liver cloudy swelling and fatty change. Cultures from lung, heart, and pus in the pleural cavities gave a pure growth of *Bacillus coli*.

* This paper formed part of a report on "Stillbirth, its Causes, Pathology, and Prevention" to the Medical Research Council, Nov. 1921.

The condition was therefore pneumonia and empyema with septic endocarditis, and the short duration of illness, the condition of the child at birth, and the finding of the *B. coli* as the infecting organism, seem to point to the infection being an ante-natal one, due to premature rupture of the membranes allowing infection of the liquor amnii. It should be stated that the mother's puerperium was perfectly normal, and there was not the slightest rise of temperature throughout. These two cases seem to prove the possibility of ante-natal infection and even of ante-natal pneumonia.

Condition of the Lungs.—The following tabular statement shows the condition of the lungs in the 21 cases, determined after naked-eye and microscopic examination:

Ordinary catarrhal pneumonia (1 with pleural effusion, 2 with empyema)	11
Interstitial pneumonia with catarrhal pneumonia superadded	2
Catarrhal pneumonia (patchy) plus haemorrhage into alveoli and bronchi	1
Acute congestion and oedema of the lungs with haemorrhage into alveoli and bronchi	5
Interstitial plus catarrhal pneumonia plus haemorrhage into alveoli and bronchi	1
Interstitial pneumonia plus congestion and haemorrhage into alveoli and bronchi	1
Total	21

All the catarrhal pneumonias were in a fairly advanced stage—red or grey hepatization. The alveoli contained chiefly large flattened endothelial cells, generally phagocytic and containing pigment, probably derived from red blood cells, red blood corpuscles, or even a complete polymorphonuclear leucocyte. There were generally exceedingly few polymorphs present, and this applied to all stages, though in the early cases they were slightly more plentiful. This absence of polymorphs shows that in the young infant there is little or no defence against the infecting agent. Red blood cells, generally with pigment, an occasional lymphocyte, a little fibrin and granular debris, were the only other contents. To the naked eye the lung in many of the cases of catarrhal pneumonia presents a somewhat deceptive appearance—namely, it may seem on removal from the chest to be well aerated, be crepitant, float buoyantly in water; and on section appear to be only slightly congested and oedematous. It is only on microscopic examination that the true state is discovered and a patchy catarrhal pneumonia revealed.

There were two cases of interstitial pneumonia with catarrhal pneumonia in patches superadded. The thickened alveolar walls of the former, with the poorly distended alveoli containing catarrhal cells, make it very difficult to distinguish, even microscopically, from the patches of catarrhal pneumonia, but in the former the cells in the alveoli are phagocytic endothelial only, derived from the lining of the alveoli, with the addition of a few red cells. The cells are comparatively few in number and are loosely arranged, while in the latter there are in addition to the endothelial cells many red blood corpuscles, fibrin, with a few polymorphs and lymphocytes, and the mass fills the alveolus more completely, giving to the part a much more solid appearance.

Signs and Symptoms.

In none of these cases of pneumonia had its existence been suspected before death and post-mortem examination. There was no rise of temperature, no notable degree of cyanosis, nor rapidity of breathing except in the case of No. 5, where blueness and rapidity and difficulty of breathing had been present from birth, and was naturally ascribed to atelectasis. In this case, too, the abdomen had been somewhat distended, though it is not clear if this sign was also present from birth. A history is generally obtained that the child seemed to be slightly blue and its extremities cold, and did not cry strongly or feed well. In one case where such symptoms were present I was able, on examining the bases of the lungs behind, to find well-marked tubular breathing, and thus a tentative diagnosis of pneumonia was made, though the child at that time was only 30 hours old. It died six hours later, and at post-mortem examination both lungs were found to be consolidated. This, however, was an unusually favourable case, and it is probable that in the usual type of patchy catarrhal pneumonia no definite physical signs could be made out even if most carefully looked for.

Acute Haemorrhagic Pneumonia of Infants.

There were, it will be noticed, six cases in which there was congestion with more or less oedema of the lung associated

with haemorrhage into the alveoli and bronchi. Five of these occurred in previously healthy lungs, while in one there was a precedent interstitial pneumonia. The blood in these cases is invariably fresh, and has evidently been poured out just before death. Its amount varies, sometimes tightly filling the alveoli and bronchi over a large area of lung, in other cases filling the alveoli more loosely. There is always a corresponding amount of blood extravasation in the alveolar walls. There is at the same time a certain amount of catarrh of the endothelial cells lining the alveoli, so that the latter contain a few large flattened endothelial cells, generally containing pigment, and similar endothelial cells are found in the alveolar walls. Very rarely is there any actual catarrhal pneumonia in these cases. Sometimes the congestion is accompanied by intense oedema. In 4 of these cases death occurred suddenly: in 3 of these 4 it was preceded by epistaxis; the fourth occurred at the patient's home and no observation was made. The course of events seems to be as follows:

The first stage is that of lung congestion—general, or limited to certain areas. The fragile foetal vessels are unable to stand the strain of the sudden inrush of blood and consequently give way, and blood is poured out into the alveoli and bronchi. The child has generally up to this point appeared to be perfectly well, or at least is so till within an hour or less of death. Death occurs suddenly, probably due to the haemorrhage, and is immediately preceded by epistaxis. The child is blanched; there is no cyanosis, therefore the blood is of different origin from that found in cases of catarrhal pneumonia, where the blood comes from the congested nasal mucous membrane. In the haemorrhagic cases the blood comes from the lung itself, and traces of it may be found on examining the upper air passages. The presence of blood in the alveolar walls of the lung precludes the possibility of that in the alveoli and bronchi having been swallowed; besides, on careful examination one can find some capillaries that have been ruptured and from which blood had been flowing when death occurred.

Neither syphilis nor prematurity seems to be a necessary factor in the causation of these intrapulmonary haemorrhages. One of the six cases was syphilitic and four were premature; therefore it is probable that both of these conditions predispose to it, though in the case in which the haemorrhage was most marked the child was at full time and non-syphilitic.

Naked-eye Appearance of the Lung.—The lung appears congested and oedematous and feels rubbery and semi-solid. On squeezing the cut surface frothy bloody fluid exudes. It generally contains still enough air to enable it to float, though poorly. In the more severe cases, however, the lung or part of it (not necessarily the lower lobes, though these more frequently than the others) may be solid and of liver-like consistence, containing no air and consequently sinking in water if separated from the rest of the lung.

The Cause of the Congestion.—In only three of these cases were cultures made: in one there was a pure *Bacillus coli* infection, in one *Staphylococcus aureus*, while in the third there was no growth on blood agar, and Gram-stained sections of the lung failed to show any organism. In the last case the thymus was enlarged, and the cause of the acute congestion and oedema with resulting intrapulmonary haemorrhage may possibly be put down as anaphylactic. This case was the first which drew my attention to the condition, and, on account of its representing what appears to be a distinct type of pneumonia with certain unique clinical and pathological features, seems worthy of being reported in full. The case occurred in the practice of Dr. R. W. Johnstone, by whose permission I am able to report it. The clinical history in Dr. Johnstone's words was as follows:

"The child was the first of two healthy parents. The mother had a perfectly normal pregnancy and the infant was born exactly at full time. Labour was not difficult, and breech was employed only to improve the flexion of the head and bring it on to the perineum. The actual delivery was spontaneous. The child, a male, was lusty at birth and weighed 8 lb. 3 oz. He made quite normal progress and put on weight satisfactorily on his mother's milk. At the end of three weeks he was circumcised. Dr. Torrance Thomson gave the anaesthetic and there were no signs of anything abnormal. At 4½ weeks he was vaccinated. The vaccination took mildly and satisfactorily, and the arm never gave any trouble. When he was exactly 5½ weeks old the night nurse found him lying dead in his cot with a little frothy blood exuding from his nose and staining the pillow. She had lifted him to change the napkin half an hour previously and had noticed nothing wrong, nor had he presented any symptoms during the preceding day or evening. During the half-hour since she had lifted him the

nurse was sitting within a few feet of his cot and he had made no sound. It was only accidentally that she discovered his condition when she rose to attend to another infant and saw that he was lying slightly more over on his face than was usual. She then drew aside the curtain of his cot to alter his position and found the condition described.

"I saw the body a quarter of an hour later. The infant was quite dead, and the body rather white; there were still traces of blood in the nostrils.

"As I could offer no explanation of the tragedy I asked Dr. John Thomson to see the body with me early next morning. He likewise could offer no explanation. The parents therefore willingly consented to a post-mortem examination, which was made by Dr. F. J. Browne about twelve hours after death."

The following was the post-mortem report:

The body was that of a well-nourished male child of average size and weight. There was one healthy and dry vaccination scar on the left arm, and the circumcision wound was quite healed. The body was rather white, and there were traces of blood about the nostrils.

The brain showed no injury or congestion, and the tentorium cerebelli was uninjured.

On opening the chest the large thymus at once attracted attention. Its increase in size was not from above downwards but antero-posteriorly, in which diameter it appeared to be almost twice the normal thickness. It was slightly congested, and weighed 17 grams. Microscopically no abnormality was found. The corpuscles of Hassall were few, reticulum scarce, and lymphoid tissue very pronounced. The thyroid was normal in size, and showed no abnormality on microscopic examination. The colloid seemed normal in amount, and there was no evidence of hyperplasia.

The lungs were well expanded and generally bright pink in colour; they floated buoyantly in water, with the heart attached. The right showed slight congestion of all its parts; it was pink in colour and was well aerated. The upper lobe of the left lung had a rubbery feel and was dark red in colour. On squeezing the cut surface frothy bloody fluid exuded. The rest of the lung was slightly congested, thus resembling the right. The upper lobe contained air and floated in water when separated from the rest of the lung. There was no subpleural haemorrhage and no pleural effusion.

Microscopically.—The upper lobe of the left lung showed intense congestion and oedema, so that the alveolar walls were much thickened. The alveoli and bronchioles contained fresh blood, in many cases completely filling them, in others leaving still a small round, air-containing space in the centre of the alveolus. In most of the alveoli and bronchioles there were a few large endothelial cells containing pigment. There were no other cells present except an occasional polymorph. Many of the alveolar walls also contained extravasated fresh blood, and here also there were numerous endothelial phagocytic cells. Sections from other parts of the lungs showed a fair amount of oedema and congestion, but far less intense; all sections examined showed well-marked emphysema, which was as noticeable in the less affected parts of the lung as in those parts where congestion and oedema were very marked.

The heart was normal; it showed no sub-epicardial haemorrhages, and microscopically showed nothing unusual.

The liver was slightly congested; cells were swollen, granular, and pale, but there was no evidence of cirrhosis.

The spleen was not enlarged, but was somewhat disfluent on section.

Microscopically.—The Malpighian bodies were very well marked, but could not be definitely said to be abnormal in extent. The pulp was very oedematous and in consequence details were difficult to make out.

All the other organs were normal and the epiphyseal lines were healthy. Levaditi stained sections of the organs failed to show spirochaetes. There was thus no evidence of syphilis, though the Wassermann test was not carried out upon either parent. Except for the thymus enlargement, which was quite definite, there was no other evidence of hyperplasia of the lymphoid tissue either in chest or abdomen, neither was there the least evidence of asphyxia.

Cultures from the left lung and from the liver on blood agar were sterile, and Gram-stained sections of the lungs failed to show any organism.

The presence of the large amount of oedema in this case was noteworthy; in no other case was it anything like so marked. It was a yellowish opaque fluid that could easily be seen in the stained section by the naked eye. The other cases showed none of this, but congestion and haemorrhage only. In none of the other cases was the thymus enlarged, nor was there evidence of hyperplasia of the lymphoid tissue elsewhere. In two, however, there were peculiar appearances in the thyroid. The child in the former case had been found in the thyroid. The child in the latter case had been found dead in bed with the mother at the age of 10 days. It had been born at full time, had always seemed perfectly healthy, and had been in its usual good health the night previous to its death. Suspicion of overlaying naturally arose. Of this, however, there was no evidence, and the lung showed intense congestion and haemorrhage into the alveoli and bronchi. The thyroid contained no colloid, and the cells lining the acini were shed into the lumen. A similar appearance was found in another case, where there was also, however, fairly

well marked though patchy fibrosis of the thyroid, though there was no other reason to suspect the case as syphilitic, and the other organs showed no syphilitic change.

It would seem, therefore, that where—especially in a premature or syphilitic infant, in which the vessels are particularly apt to give way under strain—a fairly acute congestion of the lungs occurs, the capillaries in the alveolar walls may give way and suddenly flood the air passages (alveoli and bronchi) with blood, invariably causing sudden death, the only preceding physical sign being the blanching of the skin and epistaxis. The congestion may be due to an organism of normal or increased virulence, or it may occur in the absence of any organism and may then be possibly of the nature of an anaphylaxis. The condition is not limited to premature or syphilitic infants, but may also occur in full-time and previously healthy infants, though in these the congestion probably requires to be more acute and of greater degree. This "acute haemorrhagic pneumonia of infants" forms a distinct clinical and pathological entity and accounts for many of the sudden deaths occurring in infants previously apparently healthy.

Summary.

1. Pneumonia is a common cause of death amongst infants during the first week after birth, and accounted for 21 deaths out of 80, or 26 per cent.

2. It is sometimes due to ante-natal infection from premature rupture of the membranes, and the infant may be not only infected but also suffering from an advanced stage of pneumonia before its birth.

3. In the infant there is little defensive reaction as compared with the adult against the infecting agent.

4. Pneumonia in the first few days of life is an extremely insidious disease, generally presenting no characteristic symptoms which might lead to its presence being suspected and the carrying out of physical examination.

5. Even at post-mortem examination the presence of the disease may be missed if microscopic examination of the lungs is not carried out.

6. "Acute haemorrhagic pneumonia of infants" forms a distinct clinical and pathological entity which gives rise to sudden death in children who may be apparently previously healthy, either full-time or premature. It follows acute congestion of the lungs, the fragile vessels in the alveolar walls rupturing and flooding the alveoli and bronchi with blood. The sudden death is preceded by epistaxis and blanching of the skin, and the etiological factor may be organismal or possibly of the nature of an immediate anaphylactic reaction.

7. The importance of avoiding premature rupture of the membranes during labour, and of taking every precaution to safeguard the newly born infant against infection, cannot be over emphasized.

A CASE OF DISSECTING ANEURYSM OF THE AORTA.

BY

SIR HENRY DAVY, K.B.E., C.B., M.D., F.R.C.P.,

AND

MABEL GATES, M.D. LOND.

[With Special Plate.]

THE patient, a man aged 55, had usually enjoyed good health. He was a married man with three grown-up healthy children, and had led a very active life as a master baker; he frequently lifted heavy weights (large baskets of loaves, etc.) in his business. Once a month he went to London and back in the day to attend a meeting as a director.

He first consulted Sir Henry Davy in June, 1914, for papular eczema on his right leg and left arm; the papules in many places formed small sores, but were easily cured with ordinary treatment. In 1915 and 1916 he was seen twice with two attacks of slight influenza. In 1919 he had a rather severe bleeding from the nose, and was attended by Dr. Andrew. A few months after this he had another attack, when he was sent to Mr. Worthington, who found and speedily cured an ulcer on one of the nostrils. He was seen twice in 1920 with a return of his rash, and then it was noted that he had a rather high blood pressure (180 and 185), but he quickly got rid of the rash and was under no medical attendance from December, 1920, until November, 1921.

History of Attack.

On October 31st, 1921, he felt quite well, and went to London, leaving Exeter by the 7 a.m. train, and returning at 9.30 p.m. He went to bed, slept well, and got up and went to business the next morning as usual. There is no clear history of what work he did that morning.

About 10 a.m. on November 1st he felt discomfort in his chest and stretched his arms backwards. Almost immediately he was seized with intense pain in the region of the heart and became very ill indeed. Dr. Mabel Gates, who attends his wife and daughter, saw him almost immediately. She found him "with intense pain in the region of the heart, collapsed and sweating, with a quick irregular pulse, and apparently dying." Sir H. Davy joined Dr. Gates just before 11 a.m., and found that the patient had somewhat recovered under her treatment with amyl nitrite. His pulse was very quick, but regular. He was pale and somewhat collapsed. He complained of a sharp intense pain, which he said started from the nipple in front and passed straight to almost the same level of the spine behind. This pain prevented his keeping still for a minute. He was constantly up and down in bed, and in and out of it, trying by change of position to get ease.

As the pain continued in spite of nitroglycerin and amyl nitrite, he was given an injection of morphine gr. 1/5 at about a quarter to 12, after which the restlessness nearly ceased, although he still said he was in pain. When we saw him again together at 9 p.m. he was quiet, his pulse had recovered considerably, and was 64 to the minute, and his temperature was subnormal, 97°. He still, however, complained of pain. Up to this time we could not examine him at all thoroughly: he was too restless and too ill. But on superficial examination of the heart and lungs there was nothing very definite to be found. We ordered another injection of morphine gr. 1/4, to be repeated after six hours if necessary.

Discussing the condition together, we could not arrive at any definite conclusion. The pain in the region of the heart, the quick irregular pulse, together with the collapse and sweating, might have gone very well with angina. But the restlessness was altogether unlike it. At our next visit the following morning we found the conditions entirely changed. He had passed a fairly good night, sleeping at intervals, and taking a fair amount of milk and water as nourishment. The pain had not been so severe and no second injection had been needed. Examination showed—

1. The area of cardiac dullness was much increased, extending upwards to the second rib on the left side, downwards about 2½ or 3 in. below the nipple line and outwards to about 3 in. outside the nipple line.

2. The heart was visibly displaced in accordance with these measurements, being pushed downwards and outwards. The area of pulsation corresponded with the areas described, and the apex beat was in a line with the axilla.

3. There were no adventitious heart sounds, and there was no bruit over the aorta, either back or front. The blood pressure was 180.

4. On turning the patient on his side a small area of dullness was found at the base of the lung; there was a want of entry of air all over the back of the chest, and an impaired note of resonance over a much greater area than the dullness.

It was evident that we had not to do with an ordinary case of angina, and, after discussing all the symptoms carefully, we came to the following conclusions:

1. That the heart had been displaced downwards and outwards by the formation of an aneurysm in the neighbourhood of the arch of the aorta.

2. That this had developed more or less slowly with intense pain, and that therefore it was probably due to a dissecting aneurysm.

3. That the dullness at the base of the left lung showed that there was a leakage of blood into the left pleura.

The intense pain I have described led us to diagnose a dissecting aneurysm. Once before one of us had had an opportunity of observing the sudden formation of an aortic aneurysm.

A delicate lady with a very bad family history, who was accustomed to no muscular work, decided to roll her own lawn with a rather heavy new roller. After doing so for some little time she was suddenly seized with a pain in the back. Both she and her husband, who was a doctor, thought she had just strained her muscles or had rheumatism from the unusual work. I saw her ten days after, as the pain continued. Careful examination revealed a small pulsating tumour in the abdominal aorta, just above its bifurcation into the iliac arteries. In my opinion the pulsation was distinctly expansile, and I diagnosed an aneurysm which had suddenly developed during the rolling. The pain was

never very intense, but it continued. Abdominal, or for that matter any, aneurysm is so rare in a woman that neither the husband nor any of his medical friends believed in my diagnosis. Eventually the patient saw by my wish an eminent London surgeon, who scoffed at the idea of an aneurysm, and promised immediate relief by removing an ovary adherent to the aorta. However, at the operation he found no such adherent ovary, but a well-marked aneurysm, and the patient has continued to suffer pain ever since.

But this case and other recorded cases did not suffer from the intense pain and restlessness displayed in our case. Dr. Gates and I thought, therefore, that we were dealing with a dissecting aneurysm, and that the separation of the coats of the aorta was the cause of the intense pain described. A dissecting aneurysm would also more probably account for a small leakage of blood into the pleural cavity, and so for the dullness found at the base of the left pleura.

Having, then, made our diagnosis, we thought we might get confirmation of it by an x-ray photograph, and Dr. Hodgson, head of the electrical department at the Royal Devon and Exeter Hospital, having a movable apparatus that he can take to patients' houses, we asked him to take a radiogram of the chest. This he did three days after the onset, and this radiogram (see Special Plate) clearly shows an aneurysm arising near the arch of the aorta.

The patient lived for nineteen days after the onset of the symptoms, being kept quiet in bed, and his pain kept in abeyance by an injection of 1/4 grain of morphine night and morning. On two occasions during this time he had severe attacks of pain with collapse, caused once by his getting out of bed against orders, and once by his getting excited about something. The temperature was at first slightly raised (99° to 100° for four days, it was then normal for three, and then there was a rise to 101° every evening, falling to about 99° in the morning. His systolic blood pressure was at first 200 to 195, but towards the last week it varied between 162 and 159. The physical signs on the left side of the chest varied, owing to an increasing amount of fluid forming in the chest, due, as it turned out, to increasing pleuritic effusion. No bruit was to be heard over the heart or over the aorta until the day before his death, November 18th, when a well-marked humming bruit was heard over the aorta behind at the level of the fourth dorsal vertebra. On November 19th he was quiet and free from pain all the morning, but at about 4 p.m. he said he felt faint and died almost immediately. A post-mortem examination was performed by Dr. Solly, pathologist to the hospital, the next day, and his account is as follows:

The left pleural cavity was sealed by adhesions, and on opening this blood-stained fluid was seen, and a large amount of blood clot, mostly recent, but some of some days' standing, was removed. The heart was enlarged and showed hypertrophy, particularly of the left ventricle, but there was no valvular disease present. There was a definite dissecting aneurysm, about the size of a small orange, at the apex of the transverse arch of the aorta, caused by the rupture of the inner coat of the aorta at this situation, where it was definitely weakened by calcareous patches of atheroma. This dissecting aneurysm had ruptured into the left pleural cavity and so caused death from haemorrhage.

TRAUMATIC ARTERIO-VENOUS ANEURYSM.

BY

GEO. G. FARQUHAR, M.B., CH.B., F.R.C.S. ENG.,
HONORARY SURGEON, DARLINGTON HOSPITAL.

[With Special Plate.]

In October, 1918, a man aged 49 fell from a bicycle, receiving a severe blow on the right side of the crown of the head. He was unconscious for several hours. A fortnight afterwards the left eye became prominent and its vision defective. Within another week the right eye began to protrude, and he was sent into Darlington Hospital by Dr. Williams of Richmond (Yorks).

On admission his appearance was as shown in Fig. 1 (see Plate). Both eyes were in a state of extreme proptosis, the conjunctivae chemosed, oozing a bloody serum and projecting in thick rolls between the lids and the corneo-scleral junction. Both corneae had lost their lustre, and their ground-glasslike surface prevented a clear view of the fundus. The pupils were slightly dilated, and the vision in each eye was only 6/60. Speech was slow and the mental condition sluggish and depressed. The patient complained of a confused sensation in the head but no real headache. The temperature was normal, and there was no obvious sepsis about the nose or jaws to suggest cavernous sinus thrombosis. No pulsation could be detected about the orbits.

Suspecting arterio-venous aneurysm, I listened over the left temple and heard a loud systolic bruit. This was equally well heard over the right temple. Pressure over the left carotid tubercle silenced this bruit; pressure over the right had no effect. The injury had evidently caused a fracture of the base of the skull, wounding the left internal carotid artery as it lay in the inner wall of the left cavernous sinus, and producing an arterio-venous aneurysm. Through the circular sinus the arterial pressure had reached eventually the right cavernous sinus, and then proptosis became bilateral.

On October 24th I tied the left common carotid, and the intracranial bruit ceased immediately. In a few days there was less oedema of the conjunctivae, and this improvement continued steadily, the proptosis diminishing *pari passu*. In three or four weeks all oedema had disappeared, and vision in the right eye had improved to 6/6. Vision in the left eye was still only 6/60, and this cornea remained "steamed." The left eye now developed an internal squint, due probably to injury of the sixth nerve by the fracture or by the subsequent arterio-venous aneurysm. As both eyes had been immobilized by oedematous surroundings this paralysis of the sixth nerve was only evident on subsidence of the swelling and return of the mobility.

Ligature of a common carotid is said to be followed by mental symptoms in some cases. In this case no ill effect resulted; on the contrary, the patient became more alert and cheerful.

One of the photographs in the special plate shows the distressing appearance of the man on admission, and the other shows the improvement three weeks after operation. The slight swelling of conjunctiva still visible above the right lower eyelid disappeared entirely during the following week. After leaving hospital the patient was lost sight of, and no information could be gathered about the final result as regards vision of the left eye and strabismus. I am informed that a year after operation he was apparently well and engaged in his usual occupation.

PNEUMOTHORAX IN A BOY AGED 7: RECOVERY.

CLINICAL AND X-RAY REPORTS.

BY

WILLIAM B. MARTIN, M.R.C.S., L.R.C.P., D.P.H.,
TUBERCULOSIS DISTRICT OFFICER, RENT COUNTY COUNCIL;

AND

ROBERT KNOX, M.D.,
RADIOLOGIST, KING'S COLLEGE HOSPITAL.
[With Special Plate.]

PULMONARY tuberculosis as it occurs in the adult is comparatively rarely found in children. In them thoracic tuberculosis more usually manifests itself as an enlargement of the lymphatic glands at the root of the lung, a condition which can be recognized by physical examination and by radiography. The relationship between pulmonary and glandular tuberculosis and age is not yet by any means clear, and is a very wide subject which lends itself to endless discussion. Some Continental writers, quoting the findings of hundreds of autopsies, assert that tuberculous enlargement of the glands at the root of the lung in children is always secondary to a lung focus or foci.

They describe such a focus in comparison with the adult pulmonary lesion as being usually very small, and state that often in children past infancy it is found to be in a state of arrest, cavity formation having sometimes taken place before this has come about. These foci are usually situated sub-pleurally, but on account of their relatively minute size it is not surprising that clinically, or even radiographically, their presence cannot be often demonstrated, and of course this would be all the more difficult in the case of a focus situated on the diaphragmatic or mediastinal surface. I recently came across a very interesting case of pneumothorax in a boy, aged 7, who had signs of intrathoracic glandular tuberculosis without any evident pulmonary lesion which would appear to be quite possibly an illustration of such a condition. He came under notice as a "contact" to his brother, who was already attending one of the tuberculosis dispensaries under my charge for tuberculous cervical glands, and I first examined him on February 18th, 1920.

His father had an enlarged gland removed from his neck in his youth, but since that time has not shown any evidence of tuberculosis. His mother died in childhood; she is stated to have usually been in "poor health," for which apparently no definite cause had ever been assigned. There is no other history of tuberculosis in the family.

He was said to have attended school regularly, to be generally full of life and mischief, and rarely complained of anything except

occasional mild attacks of abdominal pain and distension, sometimes accompanied by diarrhoea. Occasional cough had been noticed, but no dyspnoea or sputum.

He gave me the impression of being of an unusually excitable disposition. His chest and arms were thin, but he was not much under weight for his age. It was noticed that the venous network was unusually apparent under the skin of both temporal, upper frontal, left cervical, and anterior thoracic regions. The abdomen was slightly distended, but no definite thickening, dullness, or tenderness could be made out. Two small glands were to be felt in the left anterior triangle of the neck and one in the right. Both tonsils were moderately enlarged. Paravertebral arcs of comparative dullness were elicited on light percussion in both upper intercostal regions, more particularly on the right. The breath sounds were relatively harsh over the same areas and over both upper apices, especially the right. No moist sounds were heard except an occasional rhonchus, clearing on coughing, at the left base behind. D'Espine's sign was present.

A 50 per cent. solution of old tuberculin gave a positive von Pirquet reaction. I made a diagnosis of tuberculosis of the mediastinal glands with a preponderance of infection on the right. A skiagram of the chest was not taken at the time, but Fig. 2 (see Special Plate) confirms my diagnosis and demonstrates the apparent absence of definite pulmonary disease of the usual adult type. I considered that the mesenteric and cervical glands were also infected.

He attended the dispensary again three weeks later, and there was then apparently no change in his condition. On the occasion of his next visit—four weeks afterwards—he was obviously suffering from dyspnoea, and his face and ears were slightly cyanosed. His aunt gave a history that she first noticed the dyspnoea two weeks previously, that it appeared to come on suddenly after he had been crying hysterically in a fit of "temper" for some time and that he had complained of pain in the abdomen and chest and had vomited several times. She had called in a doctor, who, she said, made a provisional diagnosis of appendicitis, and advised rest, since when the breathlessness had improved and vomiting ceased.

On examination it was seen that the previously noted subcutaneous venous engorgement had become more apparent, and the apex beat of the heart was plainly visible in the right mid-axillary line. There was no heart dullness discoverable on the left side, and the whole of that side, back, and front gave out a tympanitic note on percussion.

The right supra- and infra-clavicular regions were also tympanitic. On auscultation tubular breathing was heard in the right supra-clavicular fossa, and over the other areas of abnormal resonance the typical signs of pneumothorax were found—amphoric breathing (with the metallic quality well marked) and "bruit d'airain." The boy's chest was x rayed by Dr. Knox at the King's College Hospital, Denmark Hill, and my diagnosis of pneumothorax confirmed (see Fig. 1).

As the respiratory distress appeared to be becoming less, and as there was no anaëmia or evidence of fluid in the pleural or abdominal cavity, I decided not to attempt artificial release of the imprisoned air, even though it was evidently still exerting considerable pressure. In addition to the displacement of the heart this was indicated by the bulging of the intercostal spaces on the left side, slight convexity of the dorsal spine to the right, and the evident encroachment of the upper portion of the left pleural sac over the uppermost anterior surface of the right upper lobe.

Within a few weeks the boy regained his normal appetite and mental vivacity, and could walk about quietly without apparent respiratory embarrassment, but the physical signs showed no alteration whatever for three months, when it was first noticed that the amphoric breathing was losing its metallic quality and was not so intense.

At the end of six months after the "accident" amphoric breathing had almost disappeared, but "bruit d'airain" could still be demonstrated all over the left side, but not over the right clavicular regions as before. There was no apparent change in the position of the heart. The boy could walk about now quite easily, but still had to refrain from "playing" outside.

Nine months after the accident his chest was screened again, when it was found that the heart was still situated entirely to the right of the sternum and the left lung still appeared to be quite collapsed.

Six weeks later the amphoric breathing was found to have given place to diminished breath sounds of a normal type, and it was clinically clear that the lung was functioning to a certain extent. The apex beat of the heart was at that time seen to be just to the left of the sternum; it kept moving more and more to the left until, twelve months after the date of onset of the pneumothorax, it had practically resumed a normal position.

At the present time the breath sounds on the left are almost as full as on the right, and judging from his general condition it would never be suspected that he had been through such a severe complication. He runs about now, has tales to tell of his prowess at boxing, and evidently finds my veto against football irksome.

The condition of the chest sixteen months after the "accident" is shown in Fig. 2. The left lung and heart are seen to have almost returned to their normal positions, and—I wish to repeat—the absence of a gross pulmonary lesion; such as would almost certainly precede such a complication in an adult, is very noticeable.

The determining cause of pneumothorax in the adult is usually the rupture of a superficially placed cavity, and an explanation of the "accident" in this case might be the rupture of a small dry inactive cavity, such as that described at the beginning of this article. Another cause might have

been the caseation and cavitation of a bronchial gland and contiguously placed lung tissue resulting in the formation of a sinus between the pleural cavity and the lung. Though children as a rule bear the toxæmia of active tuberculosis well, one would have expected more definite evidence of activity before and after the "accident" if this had been the case. Nor at any time has there been the slightest evidence of pus or fluid in the pleural sac, nor any sputum.

The pneumothorax would appear to have been of the valvular variety, the "flap" of the valve eventually becoming effectually closed. It is easier to conceive of the permanent closure of such a flap if it was composed of a piece of the free visceral pleura (evidently there were no old adhesions, as the pneumothorax was so complete) than of the efficient blockage of a sinus running through the tissues at the root of the lung, which must be involved in much chronic thickening and consequent loss of vitality and elasticity.

There is undoubted evidence of the spread of tuberculous infection by the blood stream and by direct continuity of tissue, and some apparently believe that it may spread along the lymphatics against the direction of the lymph flow; but, after all, it is an academically accepted fact that infection of a lymphatic gland is secondary to a focus situated in the area drained by that gland, a condition which in children is markedly exemplified by early enlargement of the gland.

This is the main theoretical argument in favour of the doctrine of the existence of a primary pulmonary focus in all cases of tuberculosis of the glands situated at the root of the lung.

Dr. Knox has kindly interpreted the main points shown on the excellent radiograms he has made as follows:

In Fig. 1 (posterior position) is seen the chest of a child showing complete pneumothorax on the left side. The heart and mediastinal contents, including the collapsed left lung, are displaced to the right of the dorsal spine. The right lung is somewhat compressed, the trachea is situated well over to the right side, and is oblique in direction. The diaphragm is fairly high in position on the right side and very much depressed on the left. On the fluorescent screen the movement of the diaphragm in respirations was irregular. The condition depicted is one of complete pneumothorax of the left side of the chest, with total collapse of the left lung, displacement of the heart, and the mediastinal contents to the extreme right of the thorax.

On July 19th, 1921, the patient was again examined and a very marked change observed (Fig. 2, anterior). The left lung has expanded, the right side of the diaphragm moves freely, the left side is more circumscribed in deep inspiration. The heart has not yet recovered its normal position, the apex being somewhat tilted upwards to the left. The left lung does not appear to have fully recovered its functional activity. The heart is somewhat enlarged; the right lung has expanded well. There is evidence of increased density of the roots of the lungs, particularly the right, where the glands are enlarged.

The condition revealed by the x ray examinations at various dates is extremely interesting. The duration of the symptoms extended over several months and there was no obvious improvement in the condition. The prevalence of the pneumothorax was strongly in favour of a valvular inlet into the pleural sac. The expansion of the lung seen in the later picture made it possible to determine the cause of the pneumothorax, the right root showed a considerable increase of density, and there is also evidence of a peribronchial thickening. There is evidently tuberculous infiltration of the root of the lung. This, however, could not be detected in the earlier pictures on account of the collapse of the lung upon the root.

FOREIGN BODIES IN THE GASTRO-INTESTINAL TRACT IN ACUTE APPENDICITIS.

BY

WILLIAM C. ALLARDICE, M.D., F.R.C.S.E.,
SURGEON, NORTH STAFFORDSHIRE INFIRMARY.

[With Special Plate.]

CONSIDERABLE interest having been lately displayed as regards the presence of foreign bodies in the gastro-intestinal tract, the following case seems worthy of record:

A woman, aged 35, was admitted under my care as a case of acute appendicitis. The only history given by her husband was that she had been ill for a few days, and that she had recently been in an asylum. As she had severe pain with marked rigidity in the right lower quadrant of the abdomen, operation was arranged for. When under the anaesthetic the nurse informed me that the patient said she had swallowed

a spoon and fork. It was then too late to take an x-ray photograph, so the operation was proceeded with. An incision was made in the right linea semilunaris, and on opening the peritoneum the caecum was exposed with a teaspoon impacted in the ileo-caecal valve. An incision was made in the small intestine, the spoon was extracted, and the aperture closed with two layers of catgut suture. The appendix was acutely inflamed and perforated at the apex, but was not adherent. This was removed and the stump dealt with in the usual way; the appendix contained no foreign body. The pelvis contained very offensive purulent fluid; a coil of the ileum was adherent to the back of the uterus, and more foreign bodies could be felt in this portion of the intestine. The abdominal incision was enlarged down to the pubis to gain access to this loop of bowel. This was separated from the uterus, and was brought up to the surface and packed off from the rest of the abdomen. The intestinal wall was acutely inflamed, covered with lymph, and perforated in several places. With a pair of scissors a 5-inch incision was made to include all visible perforations, and through this the following foreign bodies were removed: three pennies, three halfpennies, three pieces of spoon, the handle of a fork, one screw, one darning needle (broken), two tacks, one trouser button, one pen nib, one hairpin, four needles, three pins, and one half of a boot tip. The incision in the bowel was closed with two layers of catgut suture and two large drainage tubes were inserted, one into the pelvis and the other towards the caecum.

The patient stood the operation well and was given morphine to quieten the intestines. Rectal salines were administered, and nothing was given by the mouth except sips of water until forty-eight hours after the operation. There was profuse offensive discharge from the drainage tubes but no faecal fistula formed. Ten days after the operation she was sufficiently recovered to be taken to the x-ray department to be photographed. The accompanying plate shows the prongs of the fork in the stomach, a needle in the abdomen, three hairpins and the larger portion of the boot tip in the pelvis. Although the patient still had acute abdominal pain, and was obviously in great danger, it was not considered advisable to open up the abdomen again until her general condition had improved and the discharge from the tubes had ceased. She was kept strictly on fluid diet, and the bowels were opened every other day with enemata; she passed two hairpins in the motion, accompanied with great pain. Three weeks after the operation, the drainage tubes having been removed, and the wound being quiescent, a further operation was done. The original wound having been isolated, the abdomen was opened in the middle line below the umbilicus. A hairpin was removed from the small intestine in the pelvis, and the heel tip of the boot was found in a coil deep down in the pouch of Douglas, the latter being difficult to isolate and remove satisfactorily. The abdominal incision was enlarged up to the ensiform cartilage and the needle was felt lying between the stomach and transverse colon close to the large vessels. The point of the needle was pushed outwards and the needle extracted, a catgut suture being inserted at the point of exit. It was difficult to say exactly where the needle lay, as it seemed to have escaped from the stomach into the retro-peritoneal tissues. The fork was eventually located in the cardiac end of the stomach with the prongs entangled in the mucous membrane. It was impossible to remove it from this situation, so it was turned over on itself and pulled down towards the pyloric end of the stomach. This was opened, the fork removed, and the opening closed with two layers of catgut sutures as in the removal of the other foreign bodies. The abdomen was closed with a drainage tube in the pelvis, but, as no discharge followed, this was removed in forty-eight hours. The after-treatment was similar to that employed in the first operation, and the patient made an uneventful recovery.

The history of the actual swallowing of the different articles is, of course, unreliable; it is impossible to say how long these were in the intestinal tract. The patient said she had to break the fork and darning needle to swallow them, but managed the teaspoon whole, and had no great difficulty with the heel tips. She states that she first complained of severe pain in the abdomen one week after her discharge from the asylum, and this caused her to consult a doctor.

The onset of acute appendicitis with a teaspoon impacted in the ileo-caecal valve, the tolerance of the intestinal tract to this extraordinary collection of articles, and her eventual recovery are somewhat remarkable.

NASAL DIPHTHERIA AFTER ENUCLEATION OF THE TONSILS.

BY

B. SEYMOUR-JONES, F.R.C.S.,

SURGEON, EAR AND THROAT HOSPITAL, BIRMINGHAM.

It is an interesting coincidence that the writer has seen five cases of nasal diphtheria at the out-patient department of the Birmingham Ear and Throat Hospital during the last year, in which the tonsils had been perfectly enucleated and the adenoids removed. It is not desired to indicate that the removal of the tonsils renders a patient more susceptible to infection by diphtheria, but that, through the removal of the *locus minoris resistentiae*, the tonsils, infection may be diverted to a situation where it escapes prompt recognition by a practitioner with appropriate serum treatment; hence the patient becomes a carrier and propagates disease.

In the cases seen the initial symptoms appeared to have given rise to such little constitutional disturbance that no doctor had been consulted. Close questioning in each individual case elicited that the child had been "out of sorts" from periods ranging from one month to three. They were brought to the hospital because, as the parents expressed it, "they were getting a lot of rubbish from the nose."

In three cases the margin of the anterior nares was red and excoriated and covered with dried secretion resembling dark-brown sugar. In the other two there was no excoriation. The nasal chambers in four cases appeared dark red, with engorgement of the lower turbinates, and were covered with light-brown crusts of dried sero-fibrinous exudation. On detachment of a crust in some cases, or even on introducing the speculum into the nose, bleeding occurred. In one case the upper lip was covered with a crust below the nostrils, which on separation revealed a superficially ulcerated area. The nasal cavities in this case were profusely purulent.

A short time back the writer saw in his consulting room a boy, aged 7, who had been operated upon two years previously for tonsils and adenoids. The parents brought him because they thought that the operation had not achieved all they expected as he was still unable to breathe through the nose freely. His symptoms had been markedly aggravated the last three weeks. When examined with a nasal speculum a condition resembling lupus of the nasal septum was seen; the latter was very swollen and oedematous, with some cloudy gelatinous secretion on it, and a fibrinous membrane was seen gummy the lower turbinates to the septum. The alae were reddened in patches, and also swollen. The throat manifested no suggestive signs and appeared perfectly healthy, but there was an acute adenitis and glands could be palpated below the uvula. A swab was taken and the report stated: "Klebs-Loeffler bacillus found in profusion." It is evident from this that the membrane will persist for three weeks in the nasal cavity.

The local treatment ordered in all cases was a spray of colloidal argenticum, 1 in 2,000, six times daily. The cases were notified and it was suggested that at least 6,000 units of antitoxin should be administered.

Nasal diphtheria may exist, however, in adults without giving rise to any discomfort and to few or no symptoms.

A long-suffering and slightly resentful officer was referred to the care of the writer at the 2nd Southern General Hospital, Birmingham, as a carrier. Swabs taken at intervals from his nose showed persistence of Klebs-Loeffler bacillus, in spite of antitoxin and recent vaccine treatment. His nasal cavities on examination presented no departure from the normal, except that the mucous membrane appeared drier and, if anything, slightly atrophic. In his case the writer suggested enucleation of the tonsils, a spray of colloidal argenticum, and continuation of the vaccine injections.

There is ground for the presumption that nasal diphtheria may be a considerable factor in the causation of atrophic rhinitis, owing to its occurrence in children when the nose is growing, the turbinal bones in process of development, the arteries thin-walled, and the mucous glands immature. The diphtheritic toxins may act on the olfactory, sensory, and vasomotor nerves of the mucous membrane, paralysing them, and consequently inducing trophic changes by inhibiting the central impulses which govern growth. The atrophic changes and lack of development appear in the form of atrophic rhinitis, or ozaena. It is within the bounds of possibility that, in addition to other infections, such as influenza, may cause local atrophy of the mucous membrane by acting on the nerves, while other toxins derived from pneumococcus, staphylococcus, etc., cause stimulation of nerve fibres and overgrowth—local hypertrophies.

SARCOMA OF AN UNDESCENDED (ABDOMINAL) TESTICLE.*

BY

G. H. EDINGTON, D.Sc., C.M., F.R.F.P.S.G.,

VISITING SURGEON, WESTERN INFIRMARY; LECTURER IN CLINICAL SURGERY, UNIVERSITY OF GLASGOW.

THE specimen exhibited was an example of malignant disease of an undescended testicle.

The patient was a labourer, aged 49, sent to see me at the Western Infirmary in July, 1920, with a complaint of pain, of several months' duration, in the left side of the abdomen. The pain, dragging in character and coming on after strenuous work, followed and was attributed by the man to an operation in another hospital two years previously for varicose veins in the left lower limb.

First Operation.

On one occasion swelling was observed in the left groin. On examination no hernia was found, but the left scrotum was empty and there was a small scar in the left groin. There was also an operation scar in the middle of the inner aspect of the thigh.

The inguinal region was exposed by incision, and a small fatty inguinal sac was found projecting from the external ring. The sac and some accompanying vessels were drawn down, ligated, and removed. There was no trace of vas deferens or of testicle.

Second Operation.

The man was readmitted in October, 1920; he complained of persistence of pain on working, extending from the left groin downwards as far as the foot, and upwards into the lumbar region. It was thought that the pain might be originating in the undescended testicle, and transverse laparotomy was performed through the outer part of the left rectus, with splitting of the internal oblique and transversalis muscles. An adherent epiploic appendage from the sigmoid colon led to a mass in the pelvis, firmly seated between the bladder and rectum. This mass was enucleated after the peritoneum over it had been opened. It had two pedicles: one, fatty and fibrous, attached to the pelvis; the other was from the spermatic vessels, about half-way along the pelvic brim. He was discharged, with the wound healed, in three and a half weeks.

The mass was a flattened ovoid, measuring 5.3 cm. x 4.3 cm. x 3 cm. It bore a general resemblance to a testicle with faintly indicated epididymis along one side. The smooth convex surface showed several losses of soft consistence which suggested cystic formations. No trace of vas deferens was seen. A histological examination of the specimen was made by Dr. Ernest Dunlop, who reported that it consisted of a highly cellular malignant tumour of sarcomatous type, with considerable areas of necrosis. In one part the remains of atrophic testicular substance were seen.

After-History.

The man reported at the infirmary in November, 1921. There were no signs of any extension of the tumour, but he stated that he still suffered from pain in the whole length of the lower limb, and that it had not yielded to treatment. The pain did not trouble him when resting. Its distribution corresponded with the nerve.

Malignant disease of the testicle, whether normally descended or not, is comparatively rare. Eccles¹ gives its frequency as 1 in 2,100 of all male admissions to a large London hospital.

The liability of undescended testicle to malignant change has long been known, and the opinion has from time to time been expressed that such liability is greater than in normally descended organs. This opinion has not been received without question. Thus, Eccles expresses the view that a greater frequency of malignant disease in imperfectly descended testicles "cannot be substantiated." When sarcoma of the arrested testis does occur it is "a disease of middle life" (loc. cit., p. 53). "In most instances an infection of the lumbar lymphatic glands takes place before any attempt at removal can be carried out... death occurs within one year of the removal of the diseased organ" (loc. cit., p. 58).

Thomson Walker,² writing in 1914, quotes the figures of various observers which support the opinion that there is greater comparative frequency of malignant disease in undescended than in descended testicles. The various series comprised all the cases of malignant disease, in both descended and undescended organs. Of Russell Howard's 57 cases, 9 were in retained testes (16 per cent.); in the Massachusetts General Hospital series of 54 cases, 6 were in retained testes (11 per cent.); and of Schadel's 41 cases, 5 were in retained organs (12 per cent.). W. B. Coley's figures³ show an even higher incidence in undescended organs. He found that the ratio of malignancy in undescended to descended is as 1 to 5.5. When these ratios and percentages are compared with the

ratio of non-descent to the normal—namely, 1 to 50 (2 per cent.)—it will be seen that the case for greater frequency of malignant growth in undescended organs is strong.

The situation of the misplaced organ calls for notice. It cannot be looked upon as arrest of the testis at any point in its normal course. No vas deferens was identified in the inguinal canal at the time of the operation on the hernia, and it might be supposed that an abnormally short vas had anchored the testicle down to the base of the bladder. Here, again, however, although there was a fibro-adipose pelvic pedicle, there was no definite structure corresponding to the vas found in it, nor was any seen in the vascular pedicle. I am therefore unable to offer an explanation of how the testis came to occupy this situation.

The tacking down of the epiploic appendage to the testicle appeared at the time to be purely inflammatory, and this is borne out by the absence, thirteen months later, of any signs of malignant disease in the region.

In the absence of any signs of enlargement of the lumbar glands, the pain complained of in the lower limb must be attributed to implication of nerve twigs in the scar of the operation for varicose veins.

The patent processus vaginalis calls for no comment. It is to be expected in all cases of departure from the normal descent of the testicle.

BILHARZIA HAEMATOBIA IN INDIA.

BY

A. H. HARKNESS, M.R.C.S., L.R.C.P.,

HONORARY MEDICAL OFFICER TO THE TYPICAL DISEASES DEPARTMENT, ST. PETER'S HOSPITAL, LONDON.

IN September last I was consulted by a man, aged 26, who complained of a urethral discharge, noticed for the first time on the previous day. It is possible that he was exposed to infection a fortnight before.

He complained of itching of the penis, and gave a history of pains in the back and frequency of micturition during the last two months. He had had a similar discharge and frequency of micturition two years earlier when on active service in India, where he was stationed for three years. This discharge persisted for two days and then disappeared completely without treatment.

I found him to be suffering from a slight greyish-white viscid urethral discharge. A smear was taken which showed a fair number of pus cells but no organisms. Rectal examination revealed an apparently normal prostate, but both vesiculae seminales were very distended. These were easily stripped, and in the urine passed after this examination bilharzia ova were first seen. A similar specimen was taken on the following day, and the presence of ova was confirmed by Mr. N. H. Johnson, who kindly made the following report: Urine, sp. gr. 1015, reaction acid; microscopic blood present, also trace of albumin and few pus cells; large numbers of spermatozoa were present; four live bilharzia ova found (*Schistosoma haematobium*).

The urethral discharge lasted two days and disappeared without local treatment. The patient was given intravenous injections of sodium antimony tartrate, in accordance with Dr. Christopherson's observations. They were given three times a week, beginning with gr. 1/2, the dose being increased by gr. 1/2 at each subsequent injection to a maximum of gr. 2, which was continued until the patient had had in all 30 grains. During the course of injections the patient remarked on a great improvement in his general health, the frequency of micturition having completely disappeared after ten grains had been administered; since then nothing abnormal has been found in the urine. After the eighth injection he complained of a feeling of nausea, and had a paroxysm of coughing after the last injection. In no other way did he experience any inconvenience during treatment.

It is considered that the patient was infected during his stay in India, and therefore that India must be an infected country. His previous trouble two years ago was really a manifestation of bilharzia.

There are very few cases recorded of undoubted bilharzia infection in India. Neumann,¹ Sanfelice, Loi,² and Frank Milton³ consider that India is an infected country. Montgomery,⁴ in 1905, stated that bilharziasis was an established disease amongst the domestic animals of northern India, and that parasites had been obtained from the horse, donkey, cattle, and sheep. He also considered that the human parasite could live in India, and that India was suitable for the propagation of the parasite. Arthur Powell⁵ reported

* Communicated to the Royal Medico-Chirurgical Society of Glasgow, January, 1922.

a case in a native of Bombay who had never left the Bombay Presidency. He stated that Major Childe, I.M.S., had also seen a few cases in Bombay, but that his patients were Iramis or Persians. Sewell⁶ describes a case of bilharzia haematobia occurring in a private of the 1st South Wales Borderers. The man had been four years in India and had never been in Egypt or South Africa. Lieutenant-Colonel D. Wardrop⁷ describes two cases of British soldiers who developed bilharzia in India six months after leaving England. Christophers and Stephens⁸ mention the case of a native infected in Madras. Most, if not all, the other cases recorded have been imported from South Africa or Egypt.

It seems clear from the case which I have reported and from the cases which have before been recorded, that bilharziasis is endemic in India, and can be contracted by Englishmen and others who sojourn in the country.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

RUPTURE OF THE EXTENSOR LONGUS POLLICIS TENDON.

DR. NORMAN DYKES'S communication on this subject in the *Journal* of March 11th (p. 387) has suggested to me the propriety of recording a case of this rare condition which I came across recently, and which presents some features of additional interest.

Mrs. I., aged 54, came to see me on November 29th, 1920, with a sprained right wrist. There was no fracture. It was treated upon the orthodox lines of bathing, massage, and movement.

She again consulted me on January 5th, 1921, because, while the general condition of the wrist was satisfactory, a fluid swelling of small size persisted over the line of the extensor longus pollicis tendon opposite the ulnar side of the proximal end of the metacarpal of the thumb. It was tender on pressure, and I advised inunction with collosol iodine oil.

A week later, on January 12th, after a morning's washing, she was seated at her midday meal and in the act of conveying food to her mouth in a spoon when a sudden and most violent "cramp" took place in her right hand—so severe as to reduce her to tears. The thumb and all the fingers were rigidly clenched and bunched in the palm, and the hand was strongly flexed on the forearm.

It was not until four or five hours had elapsed that this spasm of the flexor muscles relaxed sufficiently for her to be able to pull her hand and fingers out straight. Then she made the discovery that the thumb refused to "lay put" in the position of extension, and that she was powerless to lift it from the palm by voluntary effort.

I sent her to see Sir Robert Jones, who advised fixation in hyperextension with massage. This failed to secure return of function, and I have been unsuccessful, so far, in persuading the patient to have a tendon transplantation done.

The thumb to-day is *in statu quo*, as far as extensor movements are concerned.

The points which strike me as of special interest in this case are:

1. The antecedent injury was a sprain and not a Colles's fracture as in Dr. Norman Dykes's case and in the ten cases collected by Stapelmoehr.
2. The immediate cause of the rupture of the tendon was a muscular spasm of unusual violence and duration, affecting all the flexors of the hand and fingers, and not a slight voluntary movement as in the previously recorded cases.
3. The persistence of a local teno-synovial swelling after the general swelling and pain of the sprain had disappeared, which almost appears to support Stapelmoehr's ingenious theory of a slow necrosis of the tendon following trauma by kinking.

A. STUART MACTAVISH, M.B., Ch.B.

Penrith, Cumberland, March 13th.

The case of rupture of the extensor longus pollicis tendon reported by Dr. Dykes reminds me of a similar accident which came under my notice some years ago.

In the temporary absence of her own doctor I attended a lady, aged about 35, who had fallen on her outstretched hand while sitting. The wrist was painful, but there was no marked

deformity. I came to the conclusion that I had to deal with a Colles's fracture. This was subsequently verified by x rays. I applied a pistol-shaped splint and her usual medical attendant took charge. I did not see the patient again till some months later, and on inquiring as to her condition she told me that when the splints were finally removed and she attempted voluntary movements "something gave way" in the thumb and she, from that time, had lost the power of extending it properly, though flexion was not impaired. What happened afterwards I cannot say, as I heard no more of the matter.

In this connexion I may mention another case of rupture of a tendon which occurred without any previous injury.

A healthy lady of middle age while making a bed felt something snap in her right ring finger. Subsequently she was quite unable to extend the distal phalanx, which was flexed to a right angle. I applied a straight gutter splint, but as no improvement took place I asked a surgeon to give his opinion as to further treatment. He advised an operation. On cutting down to the extensor tendon over the last phalanx it was found, as expected, to be torn across. The torn ends were sutured and the finger was again put on a straight splint. Healing took place at once, but there was no improvement in the condition at the time or later. So thin was the tendon at the point of rupture that failure to unite was not surprising.

This accident, like the previous one, is fortunately rare, and an instance of it seems to be worthy of record.

Oxford.

F. G. GARDNER.

A SELF-RETAINING TOURNIQUET FOR CRANIAL SURGERY.

HAVING used the various head tourniquets recommended by surgical authors and illustrated in surgical textbooks, I have found them more or less troublesome and often inefficient.

The usual tourniquet type needs control by a sagittal tape band to prevent its slipping downwards over the face. It is not too easily applied and the controlling band is often in the region of the intended scalp incision. The common black elastic band I have found easier to use, though too often, after its complete sterilization, it has shown a tendency to break when strained. It certainly does not require a control band, but more than one turn round the head interferes with its snugness.

The tourniquet I now use is a length—2 to 2½ feet—of the thin rubber tubing used commonly with Paul's intestinal glass tube for bowel drainage. As is well known, it is of the glover rubber variety, is easily sterilizable, and does not readily deteriorate. It can be applied very easily and firmly, and several turns round the head lie neatly superimposed.

It is very efficient, it has no tendency to slip, and does no cause damage to the integument. After taking two complete turns, as a minimum number, round the head, the free ends need not be tied; they may be simply crossed. At the point of crossing a piece of sterilized gauze (small swab) is used to envelop it, and the fixation is completed by the bite of a haemostat. The gauze prevents injury to the rubber. Needless to add, the fixation is arranged on the side opposite the operation field.

 Honorary Surgeon, Dunfermline and West of Fife
 Hospital.

TEN CASES OF MULTIPLE BIRTH IN THREE GENERATIONS.

ONE of my patients, who has had twins three times, told me recently that her sister had had her second set of twins, and, knowing that her mother had had triplets, I made further inquiries into the history of the family. As a result I have

discovered that there have been ten cases of multiple births in the family in three generations. I have attended various members of the family for the past seventeen years, and have not the slightest reason to doubt their veracity.

 Grays, Essex.

Reports of Societies.

PRIMARY EPITHELIAL CARCINOMA OF THE SKIN.

Dr. J. DARIER, the distinguished French dermatologist, delivered a lecture before the Royal Society of Medicine on March 16th on primary epithelial cancer of the skin. The chair was taken by Dr. H. G. ADAMSON, President of the Dermatological Section, who in introducing Dr. Darier, referred to the great work which he had done on the tuberculides, and said that his book, *Anatomic et Physiologie de la Peau*, was, or should be, the constant companion of every dermatologist.

Dr. DARIER, who delivered his lecture in French, said that the etiology of skin carcinomas, their experimental production, and their treatment by intensive radiotherapy, were all matters of great interest at the present time, but the point of supreme importance in practice was to be able to recognize such a carcinoma at once, and to determine its category, because both prognosis and treatment depended upon the species to which the tumour belonged. He would not concern himself that evening with sarcomas or with epitheliomas characterizing precancerous affections, dyskeratosis, naevi, and similar conditions, but would deal only with the two main groups of primary carcinomas of the skin—spino-cellular carcinoma and baso-cellular carcinoma—together with a third condition, combining elements of both of these, on which he wished to lay special emphasis.

Dr. Darier proceeded to describe the formation in each of the two recognized groups. Spino-cellular (or prickle-cell) carcinoma, or squamous epithelioma, was characterized by lobules or tumours composed of cells of the Malpighian layer with connecting strands, which underwent cornification and gave rise to epidermic prominences. This was very commonly found at the mouth, and followed hard papilloma. Its clinical appearance at first was chancroid, afterwards showing large irregular ulceration. This carcinoma often rapidly affected the lymphatic glands, and caused death in less than three years. It was very resistant to x-ray treatment. The second type, that of baso-cellular carcinoma (rodent ulcer), showed certain differences in its manner of spreading, and was frequently deeply ramifying. It was composed of basal cells, without true cornification. Clinically, its appearance was extremely variable (epithelioma pagetoid, rodent ulcer, "epithelioma bourgeonnant," etc.), and its evolution was very slow. It might go on to ulceration and horrible mutilation, but it did not become generalized, and its malignancy was entirely local. Unlike the other variety, it was extremely sensitive to x rays.

In addition to these generally recognized species, Dr. Darier described a third, which he called "l'épithélioma métatypique" (spino-baso-cellular epithelioma). He said that he had studied this variety of recent years, and he thought that although it was comparatively rare it was a variety to keep in mind in dermatological practice. The clinical appearance was very like that in baso-cellular carcinoma, but the evolution was more rapid, and the lymphatic glands might eventually be affected and the condition become generalized. The histological structure sometimes showed what appeared to be the juxtaposition of baso-cellular and spino-cellular elements, with prominences, and at other times it seemed to present an intermediate appearance, consisting clearly neither of the cells of the one variety nor of those of the other. It was very important to be aware of this mixed condition, which accounted for about 10 per cent. of the primary carcinomas of the skin. It yielded not very well to x rays, and was much less radio-sensitive than the pure baso-cellular carcinoma.

The treatment of these conditions should never be undertaken without an exact determination of the class to which a given case belonged. The spino-cellular carcinoma should be treated by surgical excision, either preliminary or complete. Recent experience had shown that this condition might occasionally clear up under massive doses of carefully selected x rays. Baso-cellular carcinoma, when seen in time, was curable by x rays or radium in large doses. The "epithelioma métatypique," treated by ordinary doses of x rays, appeared to yield at first, but later resumed its ordinary evolution. It called for treatment either by surgical excision or by intensive radiotherapy. Altogether, the treatment varied according to the variety of condition: it was governed by the histological character of the tumour, and could fre-

quently be determined only by a preliminary biopsy. Dr. Darier showed a number of lantern views, illustrating cases and histological appearances, which latter he carefully described. One case at least was brought forward in which x rays had been of use in spino-cellular epithelioma, but in others intensive radiotherapy had had to be abandoned for surgery. One case of epithelioma in the cheek, treated by intensive radiotherapy for six weeks, showed that the x rays did not avail to deal with extension in the depth of the epithelium.

Sir JAMES GALLOWAY, in expressing the thanks of the Society, said that most of those present had happy recollections of meeting their dermatological colleagues in France during the war, and, even at that time, of engaging in dermatological discussions. But of them all the most distinguished and the one to whom it was the greatest pleasure to listen was Dr. Darier. They all recognized that in the special domain of dermatological histology he was a prince. Dr. Darier influenced the school of English dermatologists in this histological direction as no other Continental or American authority had done. That evening he had brought forward a new conception in his metatypical variety of skin carcinoma. Many of them were familiar with the histological appearances to which he had drawn attention. The spino-cellular type and the baso-cellular type they knew, but the difficult cases in which there was basal-cell formation together with some indications of transition between that and a spino-cellular formation certainly gave them pause. The difficulty of this mixed type of epithelioma very commonly arose, and he was sure that whatever considered criticism of the theory there might be in the future, for the present they were all willing to adopt Dr. Darier's classification.

The vote of thanks was warmly accorded, and, in response, Dr. DARIER assured British dermatologists of the most cordial welcome in Paris.

THE PSYCHIATRIC CLINIC.

THE discussion in the Psychiatric Section of the Royal Society of Medicine on the subject of "The ideal psychiatric clinic," which was opened by Dr. HELEN BOYLE at the February meeting (BRITISH MEDICAL JOURNAL, February 25th, page 312) was continued on March 14th. Dr. Boyle's principal points were that the clinic was better situated in the town than in the country; that patients should be asked to pay according to their means, providing no one was excluded for lack of money; that without compulsory detention co-operation of the patients could be more readily obtained; and that great care should be taken to avoid confusion of the clinic with an asylum.

Dr. BEDFORD PIERCE, the President of the Section, said that he had been somewhat reluctantly convinced by Dr. Boyle's arguments. He thought that she had made out her case that if there was any detention at all the whole character of the clinic would be altered. Perhaps, however, she had hardly done full justice to the opposite position; at all events there were one or two difficulties arising out of this question of voluntarism with which she did not deal. He would like a closer definition of the "voluntary patient." If it meant only the patient who was willing and anxious to co-operate, this would exclude large numbers of people who ought to have the advantages of the clinic, and to be kept out of mental hospitals. If the term was used in a loose sense to cover confused persons who remained where they were placed, and had not sufficient volition to exercise the wish to leave, then her clinic would require a considerable alteration of the law before it could be established, because she would be receiving persons of unsound mind for profit, and he thought that the provisions of the Act would apply even if the persons paid nothing for their maintenance. It would be a very sad thing if some of the milder forms of acute cases could not be treated in the clinic. It was exceedingly vexing to have patients leave a voluntary home of this kind on account of the present state of the law, and go to a mental hospital and recover very shortly after admission. The clinic ought to provide a place of observation for doubtful cases such as these; but how could it do so if the patients were not voluntary? Another question was with regard to depressed patients, those who were cheerful one day and suicidal the next. If a person's mental state changed suddenly so that he was no longer willing to co-operate, was he to be immediately removed? Dr. Boyle, in emphasizing the cheerful character of her clinic, surely could not mean

that all patients were co-operating all the time. He was not quite convinced that through the institution of clinics such large numbers of people would be prevented from going on to asylum insanity as Dr. Boyle appeared to think. If it could be proved that the clinics would be preventive on any large scale it would go far to justify a large expenditure of public money upon them. Expense was, he feared, going to be a very serious consideration. Nevertheless, he would like an acute case to have observation without being certified.

He recalled the case of a business man who, distressed in mind about his affairs, showed some signs of mental unsoundness, and was certified. He recovered within a week of being received at the mental hospital, but he was persuaded to stay a month, and on his discharge he found that he was no longer managing director of his company because the articles of association provided that when a person became insane he ceased to act as a director; a self-seeking partner had taken his place, and he had no remedy.

Such things could be prevented if there was provision for temporary observation. He hoped that a more enlightened public opinion would grow up, and that less fuss would be made on the subject of detention, and that the more purely medical considerations would prevail.

Dr. R. G. Rows said that if cases were to be treated in clinics it was necessary to take risks and to suffer a certain amount of anxiety. He instanced one case at the Special Neurological Hospital, Tooting, where he was Director of the Section of Mental Illnesses, of a man who came in with hallucinations of sight, hearing, and smell, as well as a general confusion, and undoubtedly gave great anxiety at first, but was now better and completing his professional training as an engineer. American experience suggested that patients were willing to enter and to remain in what was practically an asylum where they would encounter every type of psychosis. He understood that at the Bloomingdale Mental Hospital, New York, in 1920, 75 per cent. of the admissions were voluntary. It was very important to have the clinic attached to a general hospital and not to an asylum. In Wisconsin a new general hospital was lately built, and it was proposed to have a psychiatric clinic in a separate building, but, funds falling short, a floor was assigned for this purpose in one of the blocks, and great benefit had followed from this arrangement, both to the psychiatrists and the general hospital staff. It was necessary that the officers should be engaged on the whole-time principle, so that a patient who felt an emotional state approaching could go to his doctor straight away. If an officer attended only on certain days, his patients had the feeling that they were deprived of all means of consultation in the intervals.

Dr. T. S. Good said that the clinic question resolved itself into the question of certifiability, and the stumbling-block was Section 315 of the Lunacy Act, which practically made it impossible to treat a certifiable patient anywhere except at a mental hospital. He recounted the cases which he had treated at his Ministry of Pensions Hospital, Oxford, since 1918. Of the 355 war pensioners treated, only six had to go into a mental hospital, and all these six had some organic disability. Of the remaining 349, some could have been certified, but about half of them at least were now known to be in full work. He had also treated 200 cases of civilians, and had had to recommend three for certification, though he might certainly have certified a larger number.

Dr. JOHN CARSWELL described the arrangement in the observation wards of the Mental Department of the Eastern District Hospital, Glasgow, where he was engaged until 1914, when he became Medical Commissioner of the General Board of Control, Scotland. The wards consisted of 50 beds, and of between 600 and 700 patients were received in a year, out of about 1,000 cases which were intimated annually to the local authority as requiring treatment on account of mental unsoundness. The certifying physician in lunacy had complete control, and decided whether any patient should be removed to the mental hospital. The patients went into the wards voluntarily, though the term should not be too strictly interpreted; but if any of them showed hostility or insisted on leaving while they still seemed to require asylum care, they were certified immediately. During the ten years ending 1914 the annual average of those discharged recovered was 251, of those improved 111, and of those sent to the asylum 228, and the death rate was something like 5.5 per cent. All this work was done in a large modern hospital abutting on to a main street of Glasgow.

Dr. MARJORIE FRANKLIN gave some account of American clinics. Several psychopathic hospitals had been established in the United States, working more or less in contact with

the universities on the one hand and with social organizations on the other.

Of the private clinics the most important was that founded and endowed by Henry Phipps in 1913, and made an integral part of the Johns Hopkins University at Baltimore. It was under the direction of Dr. Adolf Meyer, with a staff of four resident psychiatrists and four internes. Laboratories were attached to the clinic, also provision for psychotherapy, gymnastics, and instruction in handicrafts. The beds numbered 65; the maximum charge was 35 dollars a week, but most patients paid less, and some local residents were admitted free. Above the clinic proper were rooms for twenty-five private patients who paid high fees. All the patients were uncertified, and could leave on three days' notice. They came mostly through the out-patient service, on their own initiative, at the suggestion of doctors, or through social agencies. Another type of institution was the State Psychopathic Hospital at Boston, which, when she was on its staff, had 110 beds, with an out-patient department, and was supported by the State of Massachusetts. Admission was free, and the patients usually remained ten days, except in some cases of short duration and a few chronic cases. The majority of these patients came in under some legal commitment; only 17.6 per cent. were voluntary. They were classified according to their mental state on admission, and the accommodation did not allow of social classification. Not many of the educated classes nor many sufferers from slight instability took advantage of the hospital. The administrative and clinical departments were managed separately, though both were under medical control.

Dr. E. MAROTER, who has recently returned from visiting psychiatric clinics on the Continent, gave an account of some of them, though he thought that in most cases their reproduction in this country would not be possible without an alteration of the law.

The prototype was at Munich, where the clinic was a section of the university—one, in fact, of a number of special hospitals constituting the medical school. Treatment to recovery was only carried out when this could be expected in a short time. A poly-clinic for out-patients was open daily for free consultations; it was frequented by cases of neurosis and organic nervous disorders. A few cases were brought in by the police, largely for the determination of criminal responsibility. Voluntary entrance to the clinic was not equivalent to voluntary departure. He was told that the recognition of such a principle three days' notice on the part of the patient would make the system unworkable. Once having entered the clinic the patient surrendered himself to the control of the medical officer, who decided what should be done with him. The clinic was frequented by patients of every social class; one of the patients at the time of his visit was a niece of the rector of the university. The number of beds was 160, and the admissions about 2,000 annually; of these cases about 900 were transferred to asylums and 1,100 returned to their homes. The asylums which were in relation with the clinics derived 85 per cent. of their admissions therefrom. No case was refused admission to the clinic on the ground of severity, though some were refused for the opposite reason. The medical staff consisted of director, deputy director, and sixteen assistants.

At Cologne there was a similar institution, but its in-patient department appeared to act as a clearing house for the asylum at Bonn. He saw two clinics in Holland—at Utrecht and Amsterdam. These were informally recognized by law, which tacitly waived in their favour the requirement that not more than two such patients should be kept in one house. At Utrecht there were 90 beds and a medical staff of 16.

Dr. HELEN BOYLE, in replying on the discussion, said that she did not think a very strong case had been made out for compulsory detention as opposed to the voluntary clinic. She disagreed with Dr. Bedford Pierce's contention that the clinic system would make no appreciable difference to the ultimate admissions to asylums. She thought that egocentric personality and various other forms of insanity began in such an insidious and apparently insignificant way that it was very long indeed before they reached a certifiable stage; certainly this was the case with paranoiacs. She was quite sure that some of these, if taken in the early stages, could have their commencing condition postponed indefinitely, or could be alleviated to the extent of getting on in life fairly well if some method of sublimation could be found which suited them. Certain obsessional cases, of course, had sometimes to be certified.

THE CAUSE OF DEATH IN ELECTRICAL SHOCK.

In the Section of Electrotherapeutics of the Royal Society of Medicine on March 17th a discussion took place on "The pathological changes produced in subjects rendered unconscious by electrical shock." Dr. E. P. CUMMERTON, President of the Section, reminded the audience that in 1913 Jellinek of Vienna read a paper in the Section, in which he argued that the cause of unconsciousness was cessation of respiration, and that treatment should be by artificial respiration. During recent years these conclusions had been challenged by Borsttau of Berlin, who maintained that in

nearly all cases the unconsciousness was due to arrest of the circulation caused by ventricular fibrillation. It was of importance to decide what was the actual cause of unconsciousness, how to recognize death, and how to treat shock cases.

Dr. T. M. LEGGE (Medical Inspector in the Factory Department of the Home Office) said that one of the official regulations governing the generation, transformation, and use of electricity on factory premises was that there should be displayed a notice giving instructions for first aid in the event of accident. Long before this regulation came into force, however, the *Electrical Review* had issued certain notices stating what the first aid should be, and it was felt in his department that so long as they had nothing material to add to this non-official recommendation it need not be replaced by any other. But they did want to know whether anything fresh had been elicited since the classical experiments of Prevost and Battelli in Geneva in 1899—experiments which were admirably summarized by Dr. Jex-Blake in his Goulstonian lectures in 1913.¹ The protagonist of the "apparent death" theory was Jellinek, whose views seemed to be, on the whole, contrary to those borne out by the experiments of Prevost and Battelli. Jellinek was supported in this country by Dr. Reginald Morton, then President of the Section of Electrotherapeutics, and by a letter in the *Lancet* Dr. Morton caused widespread publicity to be given to the view that electrical shock was only an apparent death at first, and whatever the conditions or severity of the accident there was practically always a time during which it was possible to resuscitate the victim by artificial respiration if resorted to at once. In 1918 Professor Boruttau of Berlin attacked the "apparent death" theory, basing his argument on the statistics of deaths in which artificial respiration had been unavailingly employed, as given in the German factory inspectors' reports. Although the statistics in this country did not yield information enabling one to speak definitely, such as they were they supported the views of Boruttau rather than those of Jellinek. In 79 fatal accidents between 1914 and 1920, in which the current was of 50 volts or less, artificial respiration was mentioned as having been tried in 48, and in 41 of these cases the duration was stated: in 17 it was carried on for thirty minutes, in 22 for more than thirty minutes, and in 6 of these for over an hour and a half without recovery. In 64 non-fatal accidents artificial respiration was tried in 6, and in the 3 in which the duration was stated it was ten, fifteen, and twenty minutes. Boruttau's view was not that artificial respiration should be abandoned, but that it should be practised the moment after the accident had occurred, and continued for such time as there was evidence that there might be some result, but that it should not go on under the supposition that the death was only apparent, and the condition merely due to arrest of the respiratory centre. It appeared that the alternating current was more dangerous than the continuous (and in practice nearly all currents were alternating); that low pressures (under a voltage of 50) were more dangerous, or at least caused more deaths, than high pressures; that long contact was more dangerous than short, and a large surface of contact more dangerous than a small one; that the point at which the current entered the body, and in consequence the relative quantity passing through important organs like the medulla oblongata, was a material factor in increasing the danger of death; and that high-tension current, on the experiments of Prevost and Battelli, caused death by paralysis of the nerve centres, and low-tension current by ventricular fibrillation.

Mr. SCOTT RAM (Electrical Inspector in the Factory Department of the Home Office) said that the *Electrical Review* placard was first issued in 1894, in which year there was a report from France of the resuscitation after artificial respiration of a man who had been apparently killed by electricity. In his view the placard had been the means of saving a number of lives. In 1897 the Home Office recommended that all persons engaged in electrical works should be acquainted with the method of artificial respiration. The early public supplies of electricity were limited by Board of Trade Regulations to a pressure of 125 volts, as delivered to the consumer. About 1896 the introduction of incandescent lamps caused an alteration of the Regulations to admit of higher voltages, up to 200 and 240; also 650 volts were allowed for power purposes. Then the three-phase, alternating-current system was

introduced, and in 1909 all limitations as to pressure of supply were removed. During the last ten years there had been a great development in the use of three-phase alternating current, in the direction of increasing use and at higher pressures. In the three-phase systems of 400 volts or thereabouts between phases the neutral point was earthed, so that a person touching one conductor could not receive more than a 250-volt shock. Nearly all the fatal accidents were due to the victim touching one conductor while standing on ground which was not insulated. During the last ten years, up to 1921, the number of fatalities from low-pressure alternating current (250 volts or less) was 150. From direct current only six fatalities were recorded, and only one of these was a shock accident, the other deaths being due to extensive burns. During this same ten-year period the fatalities from higher pressures were as follows:

250 to 650 volts	29 deaths.
650 to 3,000 volts	17 "
Above 3,000 volts	31 "

Two-thirds of the fatalities (156 out of 233) were, therefore, due to low-pressure accidents. The percentage of recoveries in shock cases reported was as follows:

250 volts or less	39 per cent. recoveries.
250 to 650 volts	20 per cent. recoveries (about).
Above 650 volts	62.5 per cent. recoveries.

Last year there were only twelve fatalities; in four artificial respiration was carried out for over an hour, in seven for a shorter period, and in one not at all. One curious fact he had noticed was that recoveries seemed more frequent when the victim suffered a counter-shock. Even after a severe and prolonged shock there was recovery when at last the switching off of the current released the victim and he fell from a height. Extremely small contact might give rise to a fatal issue. He exhibited an ordinary thumb-switch which had been the cause of death, also a flexible lamp-holder. The reason why such accidents did not often happen in private houses was on account of the protection of dry wooden floors; the dangerous parts of a house were the stone-floored kitchen, scullery, and cellar. He also referred to the grave risks run by so-called "medical electricians," who knew as little about electricity as they did about medicine. In one case he found an arrangement such that if the wire were in the least faulty the whole 240 volts would go right through the person under treatment.

Dr. GOODMAN LEVY described some experiments on cats in which he had produced ventricular fibrillation by direct application of the faradic current to the heart. When a single induction shock was applied to the ventricle it produced a responsive contraction; a series of such shocks, if sufficiently slow, produced a corresponding series of responses. By gradually increasing the rate of shock, responses could be obtained in the cat's heart up to between 450 and 500 per minute. With a further increase, the ventricles responded only to alternate shocks or the heart passed into fibrillation. The onset of fibrillation might be very rapid in some cases, and in others delayed for several seconds, but it was never instantaneous—it was always preceded by a succession of responses. A single shock would cause fibrillation if thrown in at the exact refractory period of the heart. At any other phase in the cycle it would be ineffective, producing only a single extra-systole. Ventricular fibrillation was generally regarded as necessarily a fatal condition. Spontaneous recovery, however, was very frequent in some animals—not infrequent in the cat—and he believed it was not unknown in man, but it could not occur later than two minutes after the onset of the fibrillation. Artificial respiration was of no avail in stopping fibrillation, but cardiac massage was effective in the cat, although of course this was out of the question in ordinary cases of electric shock in man, and even when it could be applied it must be done immediately—within ten minutes. There was some reason for proceeding with artificial respiration, although no doubt its efficacy had been exaggerated. It was as well in obvious primary syncope to practise artificial respiration in view of the possibility of spontaneous recovery of the heart without recovery of the respiration.

Dr. BERNARD SPILSBURY said that he had made about a dozen *post-mortem* examinations in electrical shock, and had tried to trace the path of the current through the body. In almost all cases there were indications of entrance and exit by injuries and burns, and he found very constantly haemorrhages in or beneath the skin. In the majority of cases also

¹ BRITISH MEDICAL JOURNAL, 1913, i, 45, 422.

there was haemorrhage into the muscles of some part; in one case he found partial rupture of the muscle on account of the violence of the current, but he had never found injuries to bone or even haemorrhages into the pericardium of the heart. What struck him was the usual absence of any indication that the current had passed through the deeper structures of the body. In one case, an engine-driver, the current went through the head, and the meninges of the brain and spinal cord showed profuse haemorrhage; but even in this case the other viscera of the body failed to show any indication of the discharge. He thought that in many cases, at any rate where the current had not been of high voltage, the discharge might go mainly through the skin, and the shock and death were the result of the effect upon the sensory nerves of the skin. In other deaths from sudden shock, not electrical, he had found a diffuse bluish-like haemorrhage over the inner surface of the left ventricle, denoting a very superficial bruise of the heart muscle. That could only be attributed to a violent contraction of the heart at the moment of shock. But he had failed to find any such appearance in death following electrical discharge. He had not been able to find any haemorrhages in the substance of the cardiac muscle, and only in one case had he seen petechial haemorrhages on the surface of the lungs, while he did not recall any indication of the passage of the discharge through the abdominal viscera. There were many parts of the body where a sudden stimulation of the sensory nerves might produce instantly fatal results. Cases had been recorded of death following stimulation of the nasal mucous membrane, and he had himself seen a case in which death immediately followed a stimulation of the laryngeal membrane (a child swallowing a crumb which got into the passages). A comparatively slight blow on the upper part of the abdomen had been followed by death, and there were a number of cases in which some stimulation of the sensory nerves in the female genital tract had been fatal. Instant death had followed very sudden and unexpected immersion in cold water, which compared very well with electrical shock. Time after time he had verified this form of death in persons taken out of water. During the war a special constable walked into the New River on a cold dark night. He was taken out some time afterwards, and it was evident that his respiratory functions were arrested at the instant of immersion. These deaths must be due to an instant arrest of the respiratory centres at the base of the brain. The sudden contact with cold water over a large area of the skin caused such an overwhelming sensory stimulation to be conveyed to the base of the brain as to produce immediate paralysis. The most reasonable explanation of deaths occurring from electrical shock was a sensory stimulation, chiefly through the skin, though to some extent through the deeper tissues, bringing about instant paralysis of the respiratory centre. That was the justification for the use of artificial respiration. He was not prepared to say that in all cases death was only apparent, but certainly when the discharge was of low or medium voltage there must be some cases—and there might be many—in which death was at first only apparent, and went on to real death failing some active means of carrying on the essential functions of the body.

Professor J. MacWILLIAM, Regius Professor of Physiology, Aberdeen, sent a communication in which he said that there were two modes of death by electrical shock, and possibly a combination of the two: (1) arrest of respiration by paralysis of the respiratory centre; (2) overthrow of the heart's action by sudden development of fibrillation. The relative incidence of these two forms depended on circumstances, the locality of application of the current, its strength, character, and duration. In the second variety, as well as the first, artificial respiration should be carried out in order to be ready for the possible recovery of the cardiac system. Certain agencies which operated successfully in opposing the development of fibrillation were often effective in restoring normal action after fibrillation had been established. A full account of his experiments with those on animals was published in the *Proceedings of the Royal Society* for 1918. The substances were urethane, strontium chloride, adrenaline, hirudin, and pilocarpine. These were commonly injected into the cavity of the left ventricle through the apex by means of a slender needle.

After Dr. JOHN BRUCE had described a curious case in which an electrician in a Grimsby hospital had been the subject of shock, Dr. CUMBERBATCH summed up the discussion.

He said that it was evident that artificial respiration must be undertaken and continued for an hour or more. It was possible that the application of very strong vibration over the pericardium by some form of mechanical vibrator might be useful in some cases. As for an absolute sign of death, Lewis Jones's *Medical Electricity* gave it as the absence of electrical excitability of the muscles.

CAESAREAN SECTION AND ALTERNATIVE TREATMENT.

At a meeting of the Edinburgh Obstetrical Society, held on March 8th, the President, Dr. J. LAMOND LACKIE, read a communication on Caesarean section and alternative treatment. The Edinburgh school, he said, had been conservative in extending the list of indications for Caesarean section. He considered induction of premature labour unsatisfactory before the thirty-sixth week, and in a pelvis with a conjugata vera of more than 3½ in. In a patient with a conjugata vera of 3½ in. Caesarean section should be recommended, each case, however, being considered on its merits, and the age of the patient, her surroundings, and previous history being carefully studied before coming to a decision. Such circumstances as a previous craniotomy, an unsuccessful induction of premature labour, or advanced age in a primiparous patient should assist in making up one's mind in favour of Caesarean section. Induction of labour at full time was not carried out as often as it should be, and there was an enormous difference between the size and development of a head at full term and one that had gone a week or two beyond it. In Caesarean section for obstruction due to uterine fibroids either myomectomy or hysterectomy should be done at the same time on account of the risk of the tumour becoming infected. In eclampsia the ideal conditions for the operation were an elderly primipara with an undilated and nuchalable os, whose condition did not rapidly improve under medical treatment. He had not yet met with a suitable case. As regards placenta praevia, while marginal cases did well with ordinary methods of treatment, in the lateral or central variety Caesarean section gave a much lower foetal and maternal mortality, and it was probable that in future more and more of these cases would be treated by section. In concealed haemorrhage where in spite of treatment by the ordinary methods the patient became progressively worse, Caesarean section or hysterectomy was the last resort, the former giving a mortality of only 11 per cent. as compared with 46 per cent. from the latter. He did not consider prolapse of the cord sufficient indication for Caesarean section, while impacted shoulder presentation was a very rare indication, though he had carried it out in one case in which it was impossible to deliver the child by any means—even though he knew the child was dead.

Contraction of Baudin's ring preventing delivery was sometimes best treated by Caesarean section; and rigid cervix and rigid vagina were very rare indications; while hydrocephalus, hydramnios, or varicose veins never justified it. Neither ventrofixation of the uterus nor the interposition operation for cystocele should ever be indications, as these operations should not be done till after the menopause. Serious diseases endangering the mother's life—for example, heart disease or advanced tuberculosis—sometimes justified the operation, while breech presentation in primiparae, delayed first stage of labour, and albuminuria should never be looked upon as indications. He had never been convinced of the advantage of waiting till the patient was in labour, but tried to choose a day near but not quite at full time, the advantage of a dilated cervix being more than counterbalanced by proper preparations. He favoured the lower uterine segment incision, considering it an improvement on the classical operation, and had been struck by the fact that a smaller uterine incision was required, the muscles of the lower segment stretching readily and without tearing. For stitching up he used chromic catgut, and had seen no reason to change it, as he had no experience of rupture of scar. He thought that the imperfect scar depended on septic healing rather than on the suture material used. In "suspect" cases it was important to carry out thorough disinfection of vagina and cervix, not only by douching but by swabbing. After removing placenta and membranes he swabbed the interior of the uterus with eusol and then pushed packing, also soaked in eusol, through the cervix into the vagina. This was removed per vaginam at the end of the operation. Indeed,

he now carried out this procedure in every case of Caesarean section, suspect or not. In septic cases pubiotomy and craniotomy were the alternatives to Caesarean section. The maternal mortality in pubiotomy was somewhat lower than in the Caesarean operation. The patient must be a multipara, and the operation was never one of election, but should be employed only after forceps had failed. The maternal mortality in craniotomy being only 6 per cent., compared with 27 per cent. in Caesarean section in "suspect" cases, it would always hold a strong position in the treatment of such cases. Our object must therefore be to recognize the conditions present and determine early upon a proper line of treatment. Thus the number of infected or suspect cases would be reduced and craniotomy reserved entirely for cases of hydrocephalus and those in which the child was already dead.

Induction of Premature Labour.

Dr. OLIPHANT NICHOLSON next read a communication on the induction of premature labour in cases of disproportion. He said that it was important that the public should be educated to realize that difficult labour could in most cases be prevented. More important than the size of the pelvis was the relative sizes of the pelvis and the foetal head. He had for many years induced labour at from the thirty-sixth to the thirty-eighth week in practically all primiparae of between 35 and 45 years of age. In all obese women where the pelvis was slightly contracted or when children had been previously lost owing to excessive size, thyroid extract $7\frac{1}{2}$ to 10 grains daily was given in the last two months of pregnancy. In this way an easier labour was obtained, the thyroid possibly reducing the weight of the foetus or the tissues of the mother's pelvis. He did not consider external pelvic measurements of much assistance as a guide to the best method of treatment in any particular case. The diagonal conjugate was more important but was difficult to measure without an anaesthetic. An occipito-posterior position might also prevent the head engaging even when there was no actual disproportion, and, before attempting relative measurements, these cases should be rectified by external manipulation. As to the method of inducing labour, he had found separation of the membranes for some distance around the internal os either by the finger or by a large-sized Fenton's dilator act satisfactorily. The membranes should be separated extensively enough to cause a definite "show" of blood. Quinine hydrochloride in 5-grain doses every four hours for twenty-four or thirty-six hours previously, and continued after the membranes were separated, assisted in stimulating uterine action. Painless dilatation of the internal os occurred, and it was then usually advisable to accelerate matters by separating the membranes still higher up. In primiparae the best method was to pack the lower uterine segment with gauze. For this purpose the author's packer—a curved metal cannula through which ribbon iodoform gauze is passed by means of a stylet—was the best method. As the gauze was passed in it mechanically lifted the membranes from the lower uterine segment.

Dr. J. W. BALLANTYNE thought that the ante-natal department had been largely responsible for diminishing the number of high forceps operations and craniotomies and increasing the number of Caesarean sections in the Edinburgh Royal Maternity Hospital. He did not remember in any previous discussion on Caesarean section the life of the foetus being put forward so prominently. It had always been the welfare of the mother that had been considered.

Dr. HAIG FERGUSON considered that indications for Caesarean section in contracted pelvis depended less upon actual pelvic measurements than upon the relative sizes of head and pelvis. In eclampsia occurring about the seventh month, especially where the woman's condition was very serious with a rigid undilated cervix, he had saved several patients by vaginal Caesarean section, which had the advantage that it could be done safely in almost any surroundings.

Dr. R. W. JOHNSTONE thought that the bad results of Caesarean section in eclampsia were due partly to the operation being done too late, and partly to the toxic condition of the patient. To get a correct idea of its value in eclampsia the operation should be done as soon as the condition is diagnosed.

Dr. KENNIE PATERSON thought that in borderline cases of contracted pelvis great experience was necessary in order to determine the proper line of treatment. The size of the father was an important factor in estimating the probable size of the child.

TREATMENT OF UNUNITED FRACTURES.

A MEETING of the Royal Medico-Chirurgical Society of Glasgow was held on March 3rd, 1922, when Mr. DONALD DUFF made a communication on the treatment of ununited war fractures, with special reference to bone grafting, illustrated by lantern slides. Mr. Duff's points may be summarized as follows: (1) At least four months should elapse after all sinuses have healed to enable the tissues to deal adequately with any encapsuled micro-organisms. During the waiting period massage must be applied and suitable apparatus used to prevent deformity. Immediately before operation a short course of deep massage should be given as a test whether there is still latent sepsis. (2) Scar tissue should be ionized, or if extensive excised, and the gap filled by pedicle or tubed skin grafts. (3) Deformities should be corrected by plaster or apparatus before operation. (4) The most rigid aseptic technique must be adopted in operating. (5) Bone scar and interposed fibrous tissue must be removed thoroughly, in one piece if possible. (6) The inlay graft gives the best results, and must be large and have good contact. (7) Stepping or comminution gives the best results in numerous cases. (8) The limb should be kept rigid in the optimum position as regards strain on the graft for two or three months, followed by physiological work to develop growth of new bone.

Treatment of Myelogenous Leukaemia.

Dr. ADAM PATRICK read notes on two cases of myelogenous leukaemia treated by x rays. The first case was treated twice weekly for six weeks by application over the spleen. The dose given was $\frac{3}{4}$ Sabouraud pastille through a 1 mm. filter. Between April 5th and June 1st the leucocytes had fallen from 500,000 to 50,000. A further course was given from July to August and again from September to October. From October to November the thighs were treated with two exposures weekly and from December to February a further course was given over the spleen. The leucocytes varied from 50,000 to 90,000. About six weeks after the last course the patient became less well and deterioration of his blood was observed. He died towards the end of May. The second case showed 550,000 leucocytes before treatment was begun. On November 20th rays of a hardness equalling a 9-inch spark-gap, one dose 3 H., were applied over the spleen only through a filter of 4 mm. of aluminium. Six applications were made over the front and seven over the back of the spleen in the course of six weeks, and by January 28th the leucocytes were reduced to about 6,000. In the first case the large size of the spleen persisted, but in the second case there was a great diminution in size.

EMPLOYMENT OF MARRIED WOMEN.

A MEETING of the London Association of the Medical Women's Federation was held on March 15th at the Elizabeth Garrett Anderson Hospital, with Dr. MARTINDALE in the chair, when Mrs. CHALMERS WATSON and Dr. GLADYS MIALl SMITH spoke on the position of women as disclosed by the working of the Sex Disqualification Removal Act. The former described the recent action of the Glasgow Corporation in dismissing married women whose husbands were in employment, and the protest that had been made by various societies against such action, while the latter dealt more particularly with her own struggle with the St. Pancras Borough Council when that body asked her to resign her appointment on her marriage, although no condition to this effect had been included in her contract. In this protest Dr. Miall Smith was backed up by the Medical Women's Federation, the British Medical Association, and the Society of Medical Officers of Health. She was, however, dismissed from the service, though it is possible that her protest bore some fruit, as no further dismissals of married employees have since occurred in London. Dr. Chalmers Watson pointed out that the original idea of dismissing married women who were able to be supported by their husbands appeared to be a genuine attempt to alleviate the existing circumstances of general unemployment, but that actually the movement was an antifeminist one, since dismissal should be aimed at in all cases of persons, male or female, married or single, who are capable of being supported by other earners, if it were to be generally fair. The resolution recently passed in Derby by the Women's Co-operative Guild, and the report adopted at the meeting of the Executive Committee of the Labour Party on February 7th last, gave the main points against the principle of dismissal of married women whose husbands are earning a livelihood. An interesting discussion followed.

Reviews.

VENOMOUS ANIMALS AND THEIR POISONS.

IN his preface to a beautiful book in two volumes¹ on venomous animals and their poisons, recently published by the firm of Masson of Paris, Professor LAVERAN explains that the work was projected by M. Césaire Phisalix, and was commenced by him in collaboration with his wife; after his premature death in 1906 it was carried on and completed by her. The book therefore presents the result of many long years of work of both compilation and original research. The volumes have been produced in an exceptionally fine style; the paper and type are excellent, and the whole work is lavishly illustrated by drawings, a large proportion of which are original. The coloured plates deserve special mention, for they are works of art of a high order, and represent the minutest details of the animals they portray.

The volumes give a complete descriptive account of all animals known to secrete poisons, together with detailed descriptions of the poison apparatus of each animal mentioned. The chemical constitution and physiological action of the different venoms is also described.

The first volume deals with invertebrates and fishes, the chief groups described being the coelenterates, the insects, the arachnids, and the fishes. The second volume deals with amphibia and reptiles, and the greater part of it is, naturally, devoted to snakes; one of the last chapters contains a description of that zoological curiosity, the duck-billed platypus, which amongst its other oddities possesses a poisonous spur. The anatomical description of the various animals and of their poison apparatus is both full and exact. Most readers will probably be very surprised to learn how large is the number of species of animals that produce poisons.

The accounts of the chemical constitution and the physiological action of venoms are very full. Our knowledge of these difficult questions is scanty, but the available information has been collected from a very wide range of sources.

It is only possible to indicate the general scope of this truly monumental work. A vast mass of facts has been brought together, and all who are interested in any way in poisonous animals or in animal poisons will have reason to be grateful. The work involved in the preparation of these volumes is indicated by the statement that their material has been gathered from the literature of the following subjects: comparative anatomy, biological chemistry, physiology, pharmacology, pathology, immunology, tropical medicine, and parasitology.

Numerous references are given in each chapter and have been taken freely from foreign as well as from French literature. We desire to emphasize the point that this book is unique, in that no work on anything approaching this scale has previously appeared giving a general account of animal poisons. The book will be of chief value probably to workers in tropical medicine, for whom it will be most valuable for reference. It will be of great interest also to all who are studying the action of poisonous proteins, for in these volumes they will find collected the very scattered and fragmentary knowledge that exists concerning animal poisons.

AN ENCYCLOPAEDIA OF UROLOGY.

THE appearance of the fourth volume of the *Encyclopédie française d'Urologie*² has been delayed by the war, and French urology has suffered the loss of the eminent man who presided at the birth of this great work—Professor Guyon. It is therefore fitting that as a frontispiece to the fourth volume there should appear an excellent engraving of the father of the French school of urology. There has also been added a short character sketch of Professor Guyon written by two of his disciples, Drs. Pousson and Desnos.

This French encyclopaedia is undoubtedly the completest work that has yet been published on urology. Volume IV, which is entirely devoted to diseases of the bladder, is a bulky volume; it is divided into two parts: the first deals with methods of examination, and the second with the etiology, morbid anatomy, diagnosis, and treatment of lesions of the

bladder. The technique of cystoscopy naturally forms an important part of the chapters devoted to diagnosis, but we are glad to see that the matter has been treated in a simple way and that the reader is not distracted, as in some works on the subject, by the introduction of difficult mathematical formulae and advanced optics. The authors of the chapter on the radiographic exploration of the bladder, by means of the injection of opaque fluids, prefer a 10 per cent. solution of collargol.

The first chapter of Part II contains a very full description of traumatic lesions of the bladder, by Drs. Rouvillois and Ferron, a chapter which has undoubtedly profited from the great experience of bladder wounds afforded by the late war; to it has been appended an extraordinarily complete bibliography that must contain some hundreds of references. Inflammations have been dealt with in the same lavish manner in the following chapter by Heitz-Boyer, whilst Drs. Desnos and Minet are responsible for the subject of calculi. In the portions of the work devoted to foreign bodies in the bladder, a most extraordinary list is given of objects found in the female bladder, ranging from a crucifix to a china doll.

Amongst the means of diagnosing vesical growths mentioned by Dr. Verhoogen is radiography. Although its range of utility is small, radiography is in certain cases undoubtedly of great service. For this purpose a 10 per cent. solution of collargol is injected, and the growth appears as a clear area infringing on the normal dark outline of the bladder. The only confusion that can arise is that due to the presence of a calculus, a large stone producing an appearance similar to a neoplasm. As a method of treatment for growths that cannot be otherwise dealt with, Verhoogen speaks hopefully of radium; he considers introduction through a suprapubic opening preferable, in the majority of cases, to cystoscopic methods. The results of total extirpation of the bladder are shown to be discouraging. Out of 69 cases, 35, or more than 50 per cent., died of the operation. Of 34 survivors 12 died during the course of the first year, 2 in the second year, and one at the end of two years. One case recorded by Hogge and Winiwarler survived six years. In 7 cases the subsequent history could not be obtained.

With regard to the treatment of papillomata the conclusions are (1) that electro-coagulation or sparking should be considered the treatment of choice in the vast majority of cases; (2) that for growths inaccessible to the operating cystoscope, or in cases of intolerance, treatment should be carried out through a preliminary suprapubic opening; (3) that when there is a doubt as to the nature of the tumour an open operation is preferable to operative cystoscopy; (4) that when several papillomata are localized in one region an open operation with excision of the whole area affected is the surest measure; and lastly, (5) that when the whole bladder is covered with vegetations, cystectomy may have to be considered; as an alternative extirpation of the mucosa, conserving the rest of the bladder wall, may be considered. The bibliography at the end of this chapter fills eight pages.

Operations on the bladder, ranging from simple lavage to total extirpation, are described, and the volume concludes with a chapter on lithotripsy, which can best be described by saying that it is as complete as the other chapters of the work.

Altogether the volume is a remarkable achievement. It is essentially a work of reference; among its greatest merits is the complete bibliography appended to each chapter. The 505 illustrations and the twelve coloured plates have been very well chosen. Drs. Pousson and Desnos, under whose direction the *Encyclopédie française d'Urologie* has appeared, are to be congratulated on the accomplishment of what cannot have been an easy task.

GUY'S HOSPITAL REPORTS.

THE first of the four quarterly parts of vol. lxxi of the *Guy's Hospital Reports*³ opens with Part I of an historical appreciation of Sir Astley Cooper by Sir Charters Symonds; this article contains interesting accounts of the old system of apprentices and dressers, who were in a different position from "the pupils" of the medical school, and of the education of a surgeon at the time when Astley Cooper was Clinician's apprentice at St. Thomas's Hospital, which was then on the

¹ *Animaux Venimeux et Venins*. By Dr. Marlo Phisalix; with a Preface by Professor Laveran. Two volumes. Paris: Masson et Cie. 1922. (Roy. 8vo, pp. 1600; 521 figures and 17 plates. 120 francs for the two volumes.)
² *Encyclopédie française d'Urologie*. Tome Quatrième: *Maladies de la Vessie*. Published under the direction of A. Pousson and E. Desnos. Paris: G. Doin. 1921. (Imp. 8vo, pp. 1151; 505 figures, 12 plates. Fr. 60.)

³ *Guy's Hospital Reports*, vol. lxxi (vol. ii, Fourth Series), No. 1. January, 1922. Edited by Arthur F. Hurst, M.D. Issued quarterly. London: Henry Frowde, and Hodder and Stoughton. (Pp. 127; 27 illustrations, 3 charts. Price: Subscription, 2 guineas post free for volume of four numbers; single numbers, 12s. 6d.)

opposite side of the street to Guy's Hospital. The accounts are appropriately preceded by a sketch of the rise of William and John Hunter as teachers at the Windmill Street school, where they succeeded Samuel Sharp, the founder of this—the first—extra-mural school. There are also thumbnailed sketches of Astley Cooper's contemporaries, and an analysis of the sterling qualities that led to his remarkable success. Dr. A. A. Osman contributes a discussion of splenic anaemia and chronic splenomegaly, based on a review of the literature and of the cases, about forty in number, in Guy's Hospital during the last twenty years; he concludes that splenic anaemia is not a specific disease but a clinical syndrome, probably always the result of a chronic infection in the spleen, which is sometimes self-limited so that spontaneous cure occurs, and is sometimes secondary to an infective focus elsewhere, removal of which may cure the disease. In his critical and independent discussion of the nature of summer diarrhoea Dr. H. C. Cameron argues that the important factor is not entirely or chiefly infective enteritis, the result of contamination of the milk supply, but is in great part the prejudicial effect of heat in lowering the need and tolerance for food, in diminishing the efficiency of the digestive secretions, and in encouraging the overgrowth and migration of bacteria which are normal inhabitants of the colon to other parts of the bowel. The injurious effects of long-continued heat on infants are considered, and four groups of clinical manifestations are described, practical measures to enable the infant to withstand the physical effects of excessive heat being recommended at the end of the article. Dr. Hugh Barber of Derby, who has done much in connexion with renal dwarfism, returns to the subject in a note on two cases of adolescent knock-knee: (1) A typical renal dwarf, (2) late rickets without obvious cause; in connexion with the first case he has unearthed an example recorded in 1833, nearly thirty years before the condition was otherwise recognized by the late Mr. R. Clement Lucas. Mr. R. P. Rowlands describes the causation, prevention, and treatment of the "vicious circle" or regurgitant vomiting after gastro-jejunostomy, and illustrates his remarks by four diagrams. The concluding article of this instalment of the reports is "The heteromorphoses in the human body" by Dr. G. W. Nicholson; it occupies fifty pages and shows much thoughtful investigation of the borderland between pathology and biology; he considers that the chief interest of the anomalies of differentiation that he has collected is the light they throw on development and growth; they suggest that differentiation is, within wide limits at all events, the result of external stimulation, of environment in fact, and that for these anomalies it is unnecessary, if not wrong, to assume an inherent vicious predisposition until all the numerous possibilities of the influence of environment have been exhausted.

LABORATORY DIAGNOSIS.

The Essentials of Laboratory Diagnosis, by FRANCIS FAUGHT, M.D., of Philadelphia, was first published in 1909, additions were made in subsequent editions, and the author says that for the now seventh edition the text has been practically rewritten.

Its popularity depends on the concise and definite manner in which the information is presented. Methods are described for the examination of sputum, faeces, and urine. There are three chapters on blood examination, including one on newer methods of analysis, in which is described the measurement of blood viscosity and the determination of the chemical composition of the blood. There is a chapter on sphygmomanometry and sphygmography also. A valuable chapter is devoted to determinations of the functions of the stomach, and a certain amount of information is given in the last two chapters on bacteriological methods and sero-diagnosis. The book is essentially a chemical and not a bacteriological handbook, but the author gives a little bacteriological information also. It would have been better to have said nothing at all than to have written the sentence which appears on page 281: "Colon bacillus decomposes sugar solutions; typhoid does not"! In a book of 500 pages it is a mistake to try to do justice to every possible branch of laboratory investigation. Those subjects which cannot be dealt with thoroughly should be omitted. For instance, the author dismisses the subject of amoebic dysentery without a word of reference to

histolytica cysts, so that the student would be led to suppose that there is no method of diagnosing amoebic dysentery if the free living amoeba is not found. What, again, is the value of descriptions of intestinal worms, to which ten pages are given, if no illustrations of their ova are provided?

The parts of the book which deal with chemical reactions are well written and well illustrated. In perusing these pages the English reader will meet with many familiar friends under the new titles by which they are known on the other side of the Atlantic. But he will also come across useful methods of analysis not commonly practised in this country, and will find them clearly explained and accurately appraised. There is very little which is not practical in the book, the only explanatory matter consisting of a few sentences stating the deductions which can be drawn from the several tests. In the majority of cases more than one method of analysis is described, and references to original articles are given. The author adds to the value of his book by embodying many personal observations and instancing technique employed in other laboratories than his own; in particular the chapter on analysis of the urine is well written, generously illustrated, and admirably arranged. An appendix contains information as to stains and chemicals, and also some tables.

It is always useful to have such a book as this at hand, and those who possess it will probably find themselves turning to it frequently.

PUBLIC HEALTH.

A SMALL textbook on medical jurisprudence, toxicology, and public health was published in 1908 from the pen of Dr. ARTHUR ROBERTSON, and the work passed through two subsequent editions. The author has now adopted the wise course of issuing a *Manual of Public Health* as a separate volume. The general arrangement is similar to that of textbooks of a like character, and the author has succeeded on the whole in carrying out his aim to include all that the average student may be expected to know. The short chapter on dietetics and foods contains a mass of accurate information, and the section on vitamins is clear. Industrial hygiene is another subject which is dealt with in an exceptionally able manner. Although the additional matter in this edition cannot be criticized, some of the older parts seem to have escaped revision. For example, on page 80 the long hopper closet is described as a cheap and good form of closet. It may be cheap, but it is a long time since it was considered good. On page 77 advantage is said to be taken in earth closets of the "deodorant" action of dry earth, but it is surely the nitrifying action which comes into play, and for this reason it is not now usual to recommend, as on page 76, fine ashes (which are sterile) from the kitchen range to be thrown over excreta in privies. The differences in the public health laws and administration in Scotland and England always seem to be a stumbling-block with the writers of public health textbooks who live beyond the border. On page 222 it is stated that "the country is divided into (1) urban, (2) rural sanitary districts. In boroughs the mayor and aldermen and burgesses; in the Improvement Act District, the Improvement Commissioners; and in a local government district, the local board form the local authority." Improvement Commissioners and local boards have been abolished in England and Wales for a generation at least, and the sanitary authorities are now the county borough councils, metropolitan and municipal borough councils, urban and rural district councils. We have no desire to be hypercritical, but we cannot refrain from referring to page 119, where some Acts of Parliament are referred to as Acts and others as bills. This must be very confusing to the student, who may also wonder why, on page 150, scarlet fever should sometimes be referred to by that name and sometimes as scarlatina. These may seem small matters, but they ought not to appear in the fourth edition of a textbook.

AN AFRICAN NATIVE MEDICAL CORPS.

The conditions produced by the war called forth all the capacity of adaptation our countrymen possessed. Not least was this so in campaigns in outlying parts of the empire. An interesting account of one of these adaptations is given in an account of the work of *The African Native Medical Corps* in

* *The Essentials of Laboratory Diagnosis*. By F. A. Faught, M.D. Seventh edition, revised and enlarged. Philadelphia: F. A. Davis and Co. 1921. (Med. 8vo, pp. xii + 523; 77 figures, 11 plates. 4.50 dollars net.)

* *Manual of Public Health*. By W. G. Aitchison Robertson, M.D., D.Sc., F.R.C.P.E., F.R.S.E. Fourth edition. London: A. and C. Black, Ltd. 1921. (Cr. 8vo, pp. 267; 25 figures. 10s. 6d. net.)

ences are, of course, partly due to differences in environment, but they must be partly innate, for they are observable in quite young children. It is difficult to account for these phenomena unless we assume that impulses can in some way become surcharged with energy from the self-preserved and race-preserved centres, and that this energy will then expend itself on any object, however unpromising, if it cannot find an outlet through an established sentiment."

Professor WEYGANDT's book on psychiatric diagnosis¹⁰ is characterized by the variety and excellence of the photographic pictures and coloured plates of lunatics of all sorts which it contains. The pictures are helped out by a clearly written and comprehensive text; full details of the methods of examination employed are given throughout. The volume may be recommended to the attention of alienists.

The *Medical Register*¹¹ for 1922 shows that the gradual increase in the number of registered practitioners, which has been noted in previous years, is still maintained. The total number on the *Register* at the end of 1921 was 45,408, as compared with 44,761 in 1920, and 44,510 in 1919. Of the total 49.52 per cent. were registered in England, 31.41 per cent. in Scotland, and 14.51 in Ireland; 4.34 per cent. of the names appear in the colonial list, and 0.22 per cent. in the foreign list. The *Register* contains for the first time the provisions of the new Dentists Act, 1921. The *Dentists Register*¹² for 1922, which has also just been published, shows that the number of dentists, 5,831, has increased from the previous year, when it was 5,610. The numbers and the qualifications of those on the *Dentists Register* will, however, be very considerably affected in the next *Register* by the provisions of the Dentists Act, 1921, which are included in this year's *Register*.

The *Minutes of the General Medical Council*¹³ for 1921 contain an account of the proceedings of the Council, the three branch councils, and the various committees, including the Dental Committee; appendices are added consisting mainly of reports of certain special committees, accounts, and the president's memorandums on Indian universities and the teaching of midwifery. A *General Index to the Minutes*¹⁴ has also been published.

¹⁰ *Erkennung der Geistesstörungen (Psychiatrische Diagnostik)*. Von Dr. phil. und med. W. Weygandt. München: J. F. Lehmann. (Sup. roy. 8vo. pp. 231; 318 figures, 18 plates. M. 34.)

ROYAL MEDICAL BENEVOLENT FUND.

At the meeting of the Committee held on February 14th 30 cases were considered and £314 voted to 27 applicants. The following is a summary of some of the cases relieved:

Daughter, aged 76, of M.R.C.S. Eng. who died in 1855. Applicant's sole income is derived from investments which bring in £21 per annum. Up to quite recently she was taken care of by her own sister, aged 74, but owing to helplessness has had to have a nurse, who is provided by friends.

in 1921. Applicant and two late husband's estate is enough to pay the creditors.

Widow, aged 44, of M.R.C.S. Eng. who died in 1921. Applicant left with five children; husband's estate is not yet settled, and up to the present the creditors have only received 15s. in the £. Applicant's share of the estate amounts to a share of the furniture only. Mother has only a home to offer, as she is entirely dependent on her married sons. Voted £15 in three instalments.

Widow, aged 59, of L.R.C.P. Lond. who died in 1933. Applicant had a home for children, but failed during the war. She received £7 7s. for looking after a small boy during the holidays and £15 from investments. Now lives with married daughter. Voted £18 in twelve instalments.

Subscriptions may be sent to the Honorary Treasurer, Sir Charters J. Symonds, K.B.E., F.R.C.S., at 11, Chandos Street, Cavendish Square, London, W.1. The Royal Medical Benevolent Fund Guild is overwhelmed, in these days of exorbitant prices for clothing and household necessities, with applications for coats and skirts for ladies and girls holding secretarial posts, and snits for working boys. The Guild appeals for second-hand clothes and household articles

for the benefit of the widows and children who in happier times would not have needed assistance. The gifts should be sent to the Secretary of the Guild, 43, Bolsover Street, W.1.

MOTOR NOTES FOR MEDICAL MEN.

By H. MASSAC BUIST.

LEGISLATION AND TAXATION.

ABOUT the time these notes are published the Government will issue the recommendation of the Ministry of Transport's Departmental Committee on the Taxation and Regulation of Road Vehicles. As regards the main points under consideration, the issue lies between two alternatives: the raising of the speed limit from 20 to 30 miles an hour, or the abandonment of any restrictions as to speed and the substitution of a system of regulations under the heading "driving to the danger of the public."

In face of the long proved fact that none can determine safety in terms of miles an hour, in that there are many circumstances in which it would be dangerous to travel at even 5 miles an hour, it is not surprising that the conclusion arrived at, and recommended to the Department as a result of this investigation, is against the use of any speed limit whatsoever. Therefore the abolition of the 20 miles an hour law is recommended. The alternative proposition, that of prosecution on the ground of driving to the danger of the public, has the theoretical disadvantage that no two individuals, or even groups of individuals, would agree as to what constitutes driving to the danger of the public. There would be prejudice in certain cases, either for or against motoring as such; altogether apart from which there is the very great difficulty of weighing evidence under this head. Therefore, very few motorists would look forward with pleasure to a bald change of conditions whereby they would become liable to be proceeded against on anybody's word as to their having driven at a certain time at a given place to the danger of the public. This point has been appreciated by the committee, and the result is that, when its report is published, it will be found that it has striven to define, otherwise to limit, what constitutes danger to the public. The matter will be gone into after the official publication. Nor is there any urgent hurry for the public to rush to conclusions on the subject, since even if the matter were proceeded with during this session, still the new law would not come into operation before the autumn at the earliest. There is even a possibility that the existing motoring laws will continue in force until New Year's Day, 1923, when the new rules will become operative. The existing laws, though they were passed in the summer of 1903, did not come into force until January 1st, 1904. Consequently precedent would be followed were the enforcement of any new regulations delayed until next New Year's Day.

MOTOR OWNERS AND THE BUDGET.

Meantime, the imminence of the Budget is causing a stir of activities among motoring bodies. Those concerned more particularly with the ownership of private vehicles are aiming to secure some change in the method of taxation. An instance of this is afforded by the set of questions sent out by the Automobile Association and Motor Union to its 150,000 odd members, each of whom is the owner either of a car or of a motor cycle. This organization has always objected to the current system of taxation on the ground that it is a levy on ownership, not on road use. It is therefore desirous of a return to the fuel tax. But, as I have pointed out in these columns on previous occasions, it seems to be impossible for a large number of reasons to revert to that. The prime reasons are that the Excise authorities could not guarantee its collection; that any such tax would have to make a differentiation in favour of home-produced motor fuels; that any such differentiation would result inevitably in some motorists escaping the payment of at least part of the tax, whereas others would pay in full, and that nobody is yet in a position to define what constitutes motor fuel. Nor is the proposition of the Automobile Association, which is carefully phrased to indicate that it is desired to substitute for the current horsepower taxes a tax on petrol, anything else than an evasion of the question. If petrol alone among motor fuels is taxed, then such a system would be most unfair to such motorists as used it, because those who ran their motor vehicles on benzol or any alternative spirit which has been, or may be, evolved and marketed for use in the liquid fuel internal

THE MEDICAL STUDENTS' REGISTER.

combustion engine, would escape the levy. It is therefore for those who desire a change in the principle of levying the motor tax to suggest some alternative to the horse-power tax other than a fuel tax. Representatives of the movement were, in fact, invited by the Government to do so at the time the law now in force was in the making. The only alternative so far suggested is a tax on tyres. But no motorist would consent to that because, whereas when he buys a tyre he may secure a perfect or a faulty one. The man who has had luck with his tyres would never be willing to pay an extra proportion of taxes on that account as well as the necessary extra sum of money to get substitute tyres. That would be multiplying his injuries. But the questions issued by the Automobile Association are, nevertheless, of interest in that the aim is to obtain from

every motorist the results of his practical experience on the road during 1921. Thus he is asked to make a return of his total annual mileage, average fuel consumption, amount of tax paid, the net period during which his car or motor cycle was out of use, and the difficulties, if any, experienced in obtaining his registration book, or licence, or both; and an expression of his personal opinion as to whether the present system of taxation "should be superseded by a petrol tax, and so on. In order to make the results of the inquiry as representative as possible, owners of private motor vehicles who are willing to assist by filling up a form, and who are not members of the Automobile Association, are nevertheless asked to send a postcard to the Secretary, 66, Whitecomb Street, London, W.C.2, asking for a form. All this information will be collated at the association's head offices and utilized in the representation it will make to Parliament.

THE MEDICAL STUDENTS' REGISTER.

REFERENCE is made elsewhere (p. 485) to the issue by the General Medical Council of the *Medical Register* and the *Dentists Register* for 1922. With them we have received a copy of another publication issued annually by the Council—*The Medical and Dental Students' Register*. This gives lists of the students registered during the year 1921, together with statistical tables and other information. A note is appended to the present edition drawing attention to the fact that on January 1st, 1923, important changes in the regulations for the registration of students will come into force. And a list is given of preliminary examinations in general knowledge which were formerly recognized but are no longer accepted. Copies of the regulations of the General Medical Council in regard to the registration of medical and dental students can be obtained from the Registrar, 44, Abchurch Lane, London, E.C.4, price 1s. 2d. post free.

An interesting feature of the *Students' Register* is the analytical summary of the medical students registered during each year in each of the three divisions of the United Kingdom from the commencement of students' registration in 1865 to the end of 1921. It records in tabular form the fluctuations in the size and distribution of the medical student body during the past fifty-seven years. We have given accompanying chart, which brings before the eye the remarkable disturbances of the past few years. It should be mentioned, however, that as registration of students is not enforced by all the licensing authorities, the totals shown throughout the chart probably fall short of the actual number of students entering in any year.

The establishment of a *Students' Register* in 1865 was one of the first steps taken by the Council of the Medical and Dental Students Registered during the Year 1921. London: Constable and Co., Ltd.

of the direct results of the Medical Act of 1858, which set up a General Council of Medical Education and Registration for the United Kingdom. It will be observed that whenever a sharp rise occurred this was soon followed by a fall, probably reflecting some apprehension about an overstocked profession in the minds of parents and guardians. For very many years the "record" entry was that of 1891, which was generally put down to the announcement of the forthcoming compulsory five years' curriculum, whereupon there was a rush of young men anxious to register as students under the old regulations. The total for that year, 2,405, was, however, exceeded by more than a thousand in the demobilization year, 1919. That year, with an entry of 3,420, represented the high-water mark of the recent flood. In 1920 the total fell to 2,531, and last year to 1,808—"a more manageable number," to use the expression of the President of the General Medical Council.

The medical schools of England, Scotland and Ireland have all shared in the decline since 1919. In that amazing year 1,375 students were registered in England, the largest ever recorded; but in Scotland the total was 1,387, which had never been approached in any previous year by any of the three kingdoms, and was 445 more than the "record" Scottish total of the previous year.

In all, during the fifty-seven years of students' registration 92,746 medical students were registered in the United Kingdom, the percentage for England and Wales being 46.86, for Scotland 33.38, and for Ireland 19.76.

It is interesting to observe a correspondence in recent years in the figures of dental students registered. The total entry of dental students in 1919 was 612, as against the previous highest figure of 351 recorded six years earlier; in the past two years the totals have been 560 and 371. Altogether since the beginning of dental students' registration in 1878 there have been rather more than 9,000 entrants.

A = United Kingdom. B = England. C = Scotland. D = Ireland.

British Medical Journal.

SATURDAY, MARCH 25TH, 1922.

COMPARATIVE PATHOLOGY.

THOSE who have watched the changes in medical practice in Great Britain during the last forty years are in a position to contrast the widespread disapproval of specialism in its initial stages with its tacit acceptance for many years past. The advice to "specialize early," against which those with a broad outlook on the science and art of medicine wisely issued a warning in the eighties, is still heard, but it is now probably more generally recognized that it has the serious disadvantage of cramping the mental horizon of the observer. There is, however, a great difference in the influence of specialism as it affects the individual observer on the one hand and the advance of medical science on the other. Increased knowledge in special directions cannot but broaden and, by providing the key to the explanation of certain problems, sometimes correct the conception of the subject as a whole. These considerations bear in some degree on the questions involved in the study of comparative pathology.

In his far-seeing address on *Elemental Pathology* to the Pathological Section of the British Medical Association at Cambridge in 1880 the late Sir James Paget pointed out the advantages that human pathology and medicine would gain from research into the diseases of plants and animals; this opinion was supported at the time by the late Sir Henry Acland, then Regius Professor of Medicine at Oxford, and Sir Clifford Allbutt since the address on Medicine he gave at the Annual Meeting of the Association in Glasgow, and indeed before that, has continued to plead for the recognition of the principle and to insist on the need for practical measures to carry it into effect. In his Presidential Address at the Annual Meeting of the Association at Cambridge in 1920 he pointed out once more that this path of research was neglected, and urged constant co-operation on systematic lines between the veterinary and medical professions.

Recent realization of the urgent economic needs of the empire for the prevention of animal disease led to the appointment in November, 1920, under the Development Commission, of an Advisory Committee on Research into Diseases in Animals, "To report on the facilities now available for the scientific study of the diseases of animals, to indicate what extension of those facilities is desirable in the immediate future in order to advance the study of disease whether in animals or man, and to advise as to the steps which should be taken to secure the aid of competent scientific workers in investigating diseases in animals." Sir David Prain, Director of the Royal Botanic Gardens, Kew, was Chairman of the Committee, which included among its members Sir William Leishman, Sir John McFadyean, Sir Walter Fletcher, and J. Martin of the Lister Insti-

tute. He held fifteen meetings and heard twenty-three witnesses, including Mr. Sheather, recently in charge of the Imperial Bacteriological Laboratory of India, at Muktesar. The annual monetary loss from diseases of animals in the United Kingdom is unknown, but it must be very large; in Scotland it is estimated to be a million sterling, and in South Africa several millions. But the importance of the matter is not

limited to the actual loss of wealth due to preventable diseases among live-stock, nor to the existence of animal infections communicable to man, for the problems of health and disease in man and in animals or plants all really belong to the same category. The report of the Committee has recently been issued.¹ It states that there is at present in the United Kingdom only one independent institution wholly devoted to the investigation of animal disease which is worthy of the name of a research institute—namely, the Research Institute in Animal Pathology at the Royal Veterinary College, London. That the state subsidy to the five veterinary colleges, which should occupy a place in relation to veterinary research similar to that enjoyed by the medical schools in relation to medical research, was no more than £3,695 in the year 1920–21 is stigmatized by the Committee as a national disgrace when regarded either from the point of view of this country's position in the stock-breeding world or from that of scientific research. It contrasts very badly with the expenditure (£123,447) upon veterinary education and research by the Government of the Union of South Africa during the same year.

The recommendations of the Committee are somewhat hesitating, and the majority of the members have clearly felt themselves hampered by the present financial stringency. They recognize that an essential part of any scheme for the improvement of veterinary research is the gradual creation of a cadre of research workers with definite prospects of tenure, pay, promotion, and superannuation benefits. The Committee advises the establishment of a Diseases of Animals Research Committee (or Board), one of the duties of which would be to establish such a cadre, but recognizes that it will be necessary to proceed with caution, keeping the needs of the whole situation under review. A number of witnesses examined by the Committee laid stress on the importance of creating chairs of comparative pathology (or comparative medicine) attached to a university, but situated neither in a veterinary nor in a medical school. Two schemes, based on the Universities of Cambridge and London respectively, were, in fact, submitted. Their promoters pointed out truly that association with a university, in addition to affording opportunity for a direct inquiry into veterinary problems and into the comparative aspects of disease as a whole, whether in man, animals, or plants, would also tend to bring into association workers in different branches of the subject, and so gradually build up a new centre for post-graduate training.

One of the members of the Committee, Mr. F. B. Smith, C.M.G., who after being professor of agriculture at the Royal Veterinary College, Wye, became Director of the Transvaal (from 1902 to 1910) and for the Union of South Africa from 1910 to 1920, when he became reader in estate management at the University of Cambridge, has attached to the report a reservation in which he strongly advocates the establishment of a chair of comparative pathology at Cambridge. His experience in South Africa convinced him of the necessity for studying animals living under the conditions in which they are usually kept, and for enlisting the sympathy of farmers. In South Africa large farms are attached to the laboratories and temporary field experiment stations are established when necessary. Owing to its situation in the midst of an agricultural district largely concerned in live-stock and light horse breeding, Cambridge is well adapted for bringing laboratory investigators into touch with the industry. During the past ten years a considerable area of land close to the town has been acquired by the university and well equipped with field laboratories, animal houses, and

¹ Report of the Advisory Committee on Research into Diseases in Animals. Development Commission, 1922. Published by H.M. Stationery Office, London. (Pp. 19. Price 1s. 6d. net.)

other conveniences for experimenting with horses, cattle, sheep, and pigs; further land could be acquired. Mr. Smith then goes on to point out the facilities for all-round study of the problems of comparative pathology that Cambridge already affords in its medical school, which has devoted attention to the study of tuberculosis in animals as well as in man; in its agricultural school, which has specialized in the physiology of the nutrition and reproduction of farm animals; in its institute of parasitology, its biochemical school, which has successfully investigated deficiency diseases, and its institutes for the study of the principles of plant and animal breeding. Cambridge already possesses many distinguished workers in various branches of science, whose collaboration would be of the greatest assistance; and, finally, the science schools turn out every year two or three hundred honours graduates, some of whom, if opportunities were forthcoming, might be attracted to veterinary research.

The Committee, however, sets aside for the present any proposal to establish a research institute in comparative pathology, owing to the cost; but expresses the opinion that when financial conditions become easier assistance from State funds towards the creation of such an institute, to serve the needs of the United Kingdom and possibly of the empire, would be justified. It says further that opportunities should be afforded on a far larger scale than at present for co-operation between veterinary and other investigators and for the free interchange of workers in medical, veterinary, botanical, and other laboratories. For England it confines itself to recommending that financial assistance should be given to the Institute of Animal Pathology attached to the Royal Veterinary College, London. In Scotland the Development Commission has already given financial assistance to the Scottish Animal Diseases Research Association to secure the maintenance of two teams of workers based on the veterinary colleges at Edinburgh and Glasgow; but the main purpose of the association is to bring to the aid of investigators the knowledge of the agricultural community, to furnish facilities for work in remote districts, and to secure that full use is made of any remedies discovered.

The Committee advises the Development Commissioners to set aside an annual sum for special researches into animal diseases; it suggests that facilities for research should be placed at the disposal of the Royal Army Veterinary Corps, and that there should be closer collaboration between officers of that corps and of the Royal Army Medical Corps.

Having rejected the proposal to establish an institute of comparative pathology in connexion with a university the Committee was rather embarrassed to know how to constitute a board to allocate grants and to supervise the research work to be carried out with them. It recommends the establishment of a mixed committee of scientific workers and stock-owners, and that this committee (or board) should for the present be dependent on the Development Commission; the hope is, however, expressed that the India Office and the Colonial Office will be willing to accept the proposed research board as an advisory body with regard to problems of research into animal diseases. In this way the board might, it is thought, come to act as a co-ordinating agency for all Government departments having interests, actual or potential, in research work of this kind.

The labours of the Committee have unquestionably advanced the subject and improved the prospects of getting established in this country a school of comparative pathology on a sufficiently wide basis and provided with adequate funds, but its recommendations do not go so far as many had hoped.

THE OPENING OF THE FOURTH SEAL

"And when he had opened the fourth seal, I heard the voice of the fourth beast say, Come and see. And I looked, and behold a pale horse: and his name that sat on him was Death."

We have received from the London office of the League of Nations a Report on the Health Situation in Eastern Europe in January, 1922, which is painful reading. It seems that the famine area, which includes the whole of the Don district, part of Southern Ukraina, and some of the Crimea, Georgia, and Armenia, supported a population of between 30 and 33 millions, of whom several millions are now, whether funds be or be not provided, beyond the reach of help owing to inadequate transport. The famine has developed in a region previously ravaged by epidemic disease—not less than 20 million cases of typhus occurred in 1919–20 in Soviet Russia and Ukraina. Relapsing fever and typhus are now increasing throughout Soviet Russia and in every part of Eastern Europe to which those leaving the famine stricken districts can penetrate. "The following figures," says the report, "illustrate eloquently the health conditions of the repatriated people when they reach the frontier. Of the 50,981 repatriated through Baranowicze in October, 804 had to be transferred to hospital and 497 died, 368 of them before admission. In November, when winter had set in in earnest, of the 59,843 repatriated, 1,227 were transferred to hospitals, while, of the 1,406 dead, 1,131 died outside the hospital. In the first week of December, of the 540 who arrived at the station, all had to be admitted to the hospital; 179 of them died—120 of them died in hospital and 59 were brought in dead. Of the 400 members of the personnel, 114 at present are down with typhus. Such is the situation in surroundings where some sanitary organization set up for the purpose does exist. It is easy to realize the state of things in the open country where no facilities of any kind are available."

The situation will, it appears, become worse, for the famine does not reach its culmination before April. Such pressure naturally made a breach in the Polish sanitary cordon, and both typhus and relapsing fever have considerably increased in that country. In Warsaw itself the notifications of typhus in December, 1921, amounted to 143 (there were 45 in November), and the first eleven days of January provided 123 cases. A centre has been discovered as far west as Bydgoszcz (Bromberg). Typhus has now made its appearance in localities which had formerly been free from it. "For example, it has extended into Lithuania, where the Government has been obliged to mobilize all the medical profession for a campaign against it. German colonists, repatriated to the eastern districts of Prussia, have introduced it in the neighbourhood of Frankfort on the Oder."

Such was the condition of Eastern Europe three years after the conclusion of the great war to end war. The rate of dissemination of typhus in Western Europe will depend upon two things: the rapidity of the decline in the standard of living and the efficiency of the sanitary cordon. The standard of living in Germany, France, and this country is declining; the great and growing volume of unemployment here is naturally correlated with dwindling individual purchasing power, less food, worse clothing, more domestic overcrowding. After the last great war—that of the Napoleonic age—the misery of the working classes here was probably greater than anything they have so far experienced in our time, and epidemic typhus duly made its appearance. We think, however, a somewhat longer latent period is to be expected, because the infestation with lice of even the unemployed populations is far less than it was a hundred years ago, and a high degree of infestation is a necessary condition of epidemic or pandemic typhus.

A CENTURY OF MEDICINE AT PADUA.

SIR GEORGE NEWMAN dedicates to the students of St. Bartholomew's Hospital, where Harvey, the most famous English scholar of Padua, was physician from 1609 to 1643, a charming address on *A Century of Medicine at Padua*.¹ The golden age of Padua was at the end of the sixteenth and beginning of the seventeenth century; with the appointment of Andreas Vesalius as Professor of Anatomy in 1538 the revival of medicine was born of observation and the study of Nature, and the inculus of authority and of the long reign of fourteen centuries of Galenic precedent was removed. The renaissance of medicine spread in the direct line from Padua to Leyden, from Boerhaave in Leyden to Edinburgh, and thence in the eighteenth century to the great medical schools in America—Philadelphia, Columbia, and New Haven. Sir George Newman describes the four Paduan pioneer teachers: Vesalius, the anatomist, who revealed morphology as the bedrock of systematic medicine; Fraeacastorius, a physician of Verona, the first of the moderns in the sciences of infection and epidemiology; Fabricius, the successor of Vesalius, not only in time but as one of the greatest of the early exponents of the elements of physiology and embryology who practised as a surgeon; and Galileo Galilei, the discoverer of the true laws of motion and initiator of the physical measurement of physiological processes. It was from Fabricius that Harvey learnt comparative anatomy, physiology, and embryology; the discoverer of the circulation must also have attended the lectures of Galileo, who was professor of mathematics, and lectured in the aula magna which adjoined the anatomical theatre. Harvey thus obtained the grounding that enabled him to apply the principles of mechanics with such good effect to the problems of physiology. But Galileo did much more than teach mathematics at Padua—he enlarged the field of man's mind, he taught the balance, so Sir George Newman reminds us, between induction and deduction as a scientific method, and advanced the far-reaching truth that all physical forces within the human body and outside it are measurable. Sir George Newman has a feeling for the picturesqueness of dates. We are reminded that Caisus was born in 1510 and Vesalius, in whose house in Padua he lived, in 1515; that Vesalius died in the year Shakespeare was born, 1564, and that Shakespeare died in 1616, the same year as Cervantes, when Harvey was giving his Lumleian Lectures at the Royal College of Physicians of London on the circulation of the blood. Sir George Newman summarizes the influence of Padua as threefold: First, it called men's minds back to Nature; secondly, it rendered inestimable service in extending the boundaries of learning while keeping ever in view the principle that to construct a true method is a larger gift to mankind than to discover items of knowledge; and thirdly, that at Padua in its wonderful century there was in science co-operation and integration of the one into the many and of the many into the one. The essay, which is imbued with the spirit and atmosphere of Padua, caught during a visit in 1921, contains two well-produced portraits of Vesalius and Harvey, and gives a picturesque reconstruction of the life and quarters at Padua of the wandering students in that far-off time.

THE MICROSCOPE IN MEDICAL RESEARCH.

MR. JOSEPH E. BARNARD, who directs the inquiries with regard to applied optics carried out for the Medical Research Council at the National Institute at Hampstead, gave an account of the work at a meeting on March 15th of the Royal Microscopical Society, of which he was at one time president. He said that fourteen microscopes were in use, and that the first problem had been to secure stability by using a heavy type of instrument and mounting it rigidly. An interferometer method was employed to test the relation of the various parts of the microscope and to obtain a quantitative

expression of any movement of the objective. No matter what the quality of the optical system, its value was thrown away by slight interferences, and accordingly it was very important to know exactly how, after any displacement, the parts could be brought back to a predetermined point. He employed a mercury-vapour lamp, with an arrangement of screens for modifying the intensity, but he had also a "Pointolite" lamp, so that a preparation could be examined in a light approximating as closely as possible to daylight. The bench was so arranged that the worker had his back to the window, for although a darkened room or any violent alteration of the general lighting was not necessary in microscopic observation, the worker should be shielded as far as possible from direct light. It was advantageous also for the wall to be covered with dead-black material and for the bench itself to be black. His mercury-vapour lamp incorporated an automatic regulating arrangement for keeping the intensity constant and preventing flicker. He believed that this lamp was of the greatest importance in microscopical work in medicine, because the dominant wave-length was short. With the carbon filament the dominant wave-length was at the red end of the spectrum, and therefore comparatively long; in the Pointolite and half-watt systems it was in the green and blue region, but with the mercury-vapour lamp it was shifted into the violet and ultra-violet. This was important with such objects as filter-passing viruses, whose diameter was really below the resolving limit of any microscope at present available for direct observation by ordinary light. Here the ordinary staining methods could hardly give a differential result, and their only effect was to decrease the transparency. The dark-ground method, in which the light was allowed to impinge on the object so that it became self-luminous, was really complementary to the other method, that of transmitted light, in which the object had to be stained or reliance had to be placed upon differences in transparency or selective absorption. But the setting up of the apparatus in dark-ground illumination had to be more finely accurate than was essential for the transmitted-light image, for, as he showed by examples with anthrax and other organisms, very slight alterations in the direction of the illumination might give most misleading appearances in the dark-ground image; an object which was really continuous, for instance, might appear as a series of points. Until quite recently the shortest radiation it had been found possible to use was one of 275 μ (a line in cadmium), but some photographs had lately been obtained with a shorter wave length, of 220 μ , permitting an effective numerical aperture of over 3. He believed that the future progress of the microscope in medicine was bound up with the use of radiation of shorter and shorter wave-lengths.

DISAPPEARANCE OF MALARIA IN DENMARK.

THE issue of *Nature* for March 9th, the appearance of which was delayed owing, as we are informed, to labour troubles, contains an interesting note on a paper on Danish mosquitos by Dr. C. Wesenberg-Lund, who has made a long and very careful research into the biology of mosquitos in Denmark. In dealing with the three species of anopheles—*A. plumbeus*, *bifureatus*, and *maculipennis*—found in Denmark, particular attention is given to the biology of *A. maculipennis*, which is regarded as the chief carrier of malaria in Europe. The author states that in Denmark this species sucks blood from domestic animals, pigs, cattle, and horses, that it is seldom seen in the open, but is found, often in incredible numbers, hanging, sluggish and blood-filled, from the ceilings of pigsties, cowsheds, and stables. Only exceptionally does it suck the blood of man, whereas in Mediterranean countries it is an outdoor species feeding largely on human blood. He considers that in Denmark *A. maculipennis*, which is there living near the northern limit of the range of the species, has ceased to be an outdoor species sucking the blood of man, and has taken to an indoor life and restricted its attacks to farm animals. This change in habits has, he thinks, been the main factor in the disappearance of malaria,

¹ *A Century of Medicine at Padua*. By Sir George Newman, K.C.B., M.D., D.C.L. London: British Periodicals, Ltd. (Pp. 23; 2 plates. Price 1s.)

the last great epidemic of which took place in Denmark in 1831. The change in the habits of the mosquito followed, he says, an alteration in agricultural methods about a hundred years ago. Whereas previously the swine had been driven to the woods to feed on mast, they and other farm animals were thereafter housed, and the stables form so many traps which attract mosquitos by the odour and heat of the animals within; once within the stable the mosquitos find all they need until the time arrives for pairing and egg-laying. Thus the connexion between man and *A. maculipennis* has been broken in Denmark, and malaria was therefore bound to disappear. The author remarks that if the measurements of the length of this mosquito given by Meigen (1818), when the species presumably fed in the open and largely on man, are correct, there has been an increase in size during the intervening century, in spite of the fact that in Denmark the species is living near the northern limit of its range.

THE EDUCATION OF THE DEAF.

THE annual meeting of the National College of Teachers of the Deaf was held in the Examination Hall, Queen's Square, on Saturday, March 18th. Mr. A. J. Story, the retiring chairman of the college, presided, and the proceedings commenced by the installation of Mr. G. Sibloy Haycock as chairman, amidst warm expressions of approval from the audience. A short address was delivered by Sir Squire Sprigge, in which the necessity for greater co-operation between medical men and the teachers of the deaf was insisted upon. He pointed out that it would be impossible to enlarge the medical curriculum in any way so as to make it compulsory upon medical students to undergo intensive training in such matters as the psychology of hearing and the technical education of the deaf. Medical education, he said, was devised to form a solid foundation of general medical knowledge, upon which the structures of different specialisms could later be erected by post-graduate training. He asked whether it would not be possible, in cities where large populations supplied alike the pathological material and the educational facilities, to form post-graduate clinics at which medical men who were anxious to undergo a special course of training in the education of the deaf could meet not only medical experts but practical and accomplished teachers of the deaf. In this way he thought a considerable number of medical men would gain an acquaintance, which they did not now possess, with the problems which are presented. Throughout the speaker dwelt upon the potential value to the population of a class of persons whose intellectual capacities were almost always normal, and in many cases extraordinarily good, but who were unable through a physical accident to enter closely into relations with society unless they could obtain special training. Mr. Frank Barnes welcomed the suggestion for proper co-operation between the medical profession and the teachers of the deaf, regretting that in the past there should have been any obstacles to such a union of effort. He emphasized the need for educating the deaf subject at the early stages, pointing out that children frequently came to schools for the deaf too late to benefit by the training; he inquired whether there should not be the same compulsory tests for hearing in elementary schools as prevailed in regard to sight. As regards medical co-operation, he approved of everything that could be done in this direction. The teacher had the child in observation year by year, gaining full information as to the mental make-up of the subject which could not possibly be in the possession of a medical man, with whom, and with whom alone for the present, it rested to decide whether the child was mentally deficient. Mr. Sibloy Haycock then delivered a presidential address, in which he spoke eloquently as to the possibilities of the expert and sympathetic education of the deaf subject, insisting upon the admirable results that could be obtained if only the training was commenced at the earliest possible date and punctiliously persevered with. In the annual report, which was adopted unanimously by the meeting, it was stated that so many graduates from the

schools for the deaf were found to be competent to proceed to higher forms of education and training that the National College of Teachers of the Deaf was preparing a scheme of training which could be run in co-operation with existing polytechnics.

MR. MONTAGU.

THE causes which led to Mr. Montagu's resignation of the office of Secretary of State for India were not in any way related to medical affairs, and we are therefore the more free to refer to the enlightened interest he showed in medical questions and in the welfare of the medical services and institutions of India. He was Under-Secretary of State for India from 1910 to 1914, and Secretary of State from 1917 till the other day. During his tenure of the senior office he on many occasions showed his determination to ensure fair and considerate treatment for the Indian Medical Service, his desire that selection for appointments should be governed by merit and not by colour, and his anxiety that the British officer and civil servant in India should have a white doctor for his wife and family. When he took office as Secretary of State the position of the Indian Medical Service was unfortunate and there was widespread discontent. The British Medical Association, after a thorough examination of the facts, came to the conclusion that the complaints it received were well founded and took up the matter vigorously. Mr. Montagu received several deputations from the Association, always with courtesy and always with the obvious desire to remedy the grievances which the Association was enabled to convince him were real. Having once made up his mind he acted with vigour, and on at least one occasion showed that he had the unusual strength of mind to realize the necessity of modifying a course he had originally intended to pursue. Throughout all the discussions he displayed an anxiety to deal fairly with the profession. In addition to adjusting many other difficulties, some of them financial and others relating to administration, he insisted on reforms designed to ensure that high medical authorities should have direct access to governors, and that their reports should not be burked or bowdlerized by the secretariat. It is not too much to say that he was the first Secretary of State for India who gave serious attention to hygiene and the prevention of disease in that country, and ever showed himself willing to give ear to suggestions on these subjects. His departure in these respects is a real loss, and we can only hope that his successor, Viscount Peel, will show a similar openness of mind and strength of character. It will perhaps not be out of place, since Mr. Montagu himself in addressing one of the deputations referred to the matter, to recall that his readiness to consider proposals affecting the scientific work of medicine and its application to practical affairs may be traced to the existence of a strong school of science in Cambridge. When an undergraduate Mr. Montagu took advantage of his opportunities in this direction, giving particular attention to the study of the sciences on which medicine rests. As to medical affairs in India, for what he desired and what he carried out Mr. Montagu deserves, and has, the thanks of the medical profession.

HUNTER AND JENNER.

JOSEPH FARINGTON, a landscape painter of considerable repute, kept a diary from 1793 to 1821, the year of his death, and the *Morning Post* is publishing a series of extracts from it. He was a son of the vicar of Leigh, in Lancashire, was born in 1745, and in 1785 became a full member of the Royal Academy, in the administration of which he took an active and influential part. He appears to have known almost every notable person of the period, including, in addition to statesmen, men of letters, artists, and society folk, John Hunter and Edward Jenner. On October 17th, 1793, John Farington made the following note on the death of John Hunter: "Much concerned at an account in the newspaper of the death of John Hunter, the eminent Surgeon, to whom I was greatly obliged in the course of last summer for his advice, etc., on account of an incised tumour on my back, which he

removed. Mr. Hunter was in the Council Room at St. George's Hospital and was suddenly taken ill, and being carried home in a closed chair expired about two o'clock. He mentioned to me once that he had some obstruction or complaint about his heart which he was well assured would cause his death suddenly at some period." The instalment of the diary published on March 17th contains the following reference to Edward Jenner, dated September 13th, 1796: "Dr. Jenner was some years ago with John Hunter, and, had Ho preferred a town life, might have been connected with him in business. Ho knows Lontherburch, and observed that Ho does not receive remarks on his work graciously. While Lontherburch was painting one day John Hunter remarked that a certain part was *too green*; 'Not green enough,' said Lontherburch, and dipping his pencil in the strongest green colour, put it on the canvas. Foote, the surgeon, became rancorous against John Hunter, because the latter had seemed to describe a hongie which Foote had invented as not necessary. To revenge himself He wrote of Hunter with much malignancy and asserted many falsehoods. Dr. Jenner has a great opinion of the Cheltenham Waters, but they may be drunk imprudently, which He sees in the countenances of many Young Ladies at the well. Above 3,000 people have drunk thom this Season; not one who came for the benefit of them has died. September 24th: Dr. Jenner has found that in *insane patients* He has moderated their violence by keeping them sick with tartar emetic. He observed that a person is more liable to take cold who suddenly removes from *cold to heat* than from *heat to cold*. Camphor water is an excellent medicine for nervous complaints."

IRISH MEDICAL SCHOOLS' AND GRADUATES' ASSOCIATION.

THE forty-fourth annual general meeting of the Irish Medical Schools' and Graduates' Association, which has now 604 members on its roll, was held on March 16th at Pagan's Restaurant, London, when Major-General Wallace Kenny, C.B., resigned the Presidential chair to Dr. James A. Macdonald, LL.D. The Council presented the annual report, which alluded to the loss by death during the past year of two very distinguished members, Major-General Sir George Eratt, K.C.B., and Sir Peter Freyer, K.C.B., who had both taken great interest in the Association after leaving India. Sir Peter Freyer had been for several years honorary secretary of the Society before becoming chairman of its Council. He was one of the first to be awarded the Association's Gold Medal. Allusion was made in the report to the effort being made by the Development Committee to bring the number on the roll up to a thousand. To the festival dinner which followed the annual meeting 117 members and guests sat down. When the usual loyal toasts were proposed the entire company stood up and sang, with marked fervour, "God save the King." The toast of "Our Defenders" was proposed by Dr. James Stewart, who said that the toast included the great number of ladies who gave their services during the war, as well as the Navy, Army, and Air Force. He coupled with the toast the names of Sir Havelock Charles, G.C.V.O., and Colonel Young, both distinguished Irishmen. Dr. Douglas proposed the health of "The Guests," which was responded to by the Honorary Secretary, the Right Honourable Edward Shortt, K.C., M.P., who mentioned one or two interesting experiences he had in Ireland when he held the office of Chief Secretary to the Lord Lieutenant. Sir Arbuthnot Lane, who proposed the health of the President and continued prosperity to the Association, said that the society by its forty-four years' experience of bringing together medical men and women of different religious and political opinions without the semblance of a quarrel showed that a calumnie influence was the *mens medica*. The President, in his reply, alluded to the fact that theirs was the first medical society in this country to admit women to membership, and that their example had done much towards inducing the British Medical Association to do likewise. The Arnott Memorial Gold Medal of the Association was presented during the course of the

banquet, by the President, to Lieut.-Colonel Robert McCarrison, I.M.S., for his scientific work, especially in connexion with deficiency disease. Squadron Leader Wm. Tyrrell, D.S.O., M.C., Royal Air Force, Miss Grace Best, and Mr. Gerald Murphy added to the attractions of the evening by several songs.

THE MAUDSLEY COURSES IN PRACTICAL PSYCHOLOGY.

IN the account published in our columns on December 17th, 1921 (p. 1051), of the course of lectures and practical instruction for the diploma of psychological medicine at the Maudsley Hospital, Denmark Hill, S.E., it was stated that the course would consist of two parts, and details of Part I were given. The details of Part II, which will commence on April 3rd, have now been published. Sir Frederick Mott will give six lectures on the pathology of mental diseases, including brain syphilis, its symptomatology and treatment, on Mondays, at 2.30 p.m., commencing on April 3rd. Dr. Bernard Hart will give eight lectures on the psychoses, on Mondays, at 4.30 p.m., commencing on the same date. Sir Frederick Mott and Dr. F. Golla will give twelve clinical demonstrations in neurology on Tuesdays, at 2.30 p.m., commencing on April 4th; the first six demonstrations will be given by Dr. Golla at the Hospital for Paralysis and Epilepsy, Maida Vale. Dr. F. C. Shrahsall will give eight lectures on the practical aspect of mental deficiency, on Wednesdays, at 2.30 p.m., commencing on April 5th. Dr. W. C. Sullivan, medical superintendent of Broadmoor Asylum, will give six lectures on crime and insanity, on Wednesdays, at 4 p.m., commencing on April 5th. Dr. C. Hubert Boud and Dr. E. Mapother will give a course of lectures on the differential diagnosis and treatment of mental disorders and the legal relationships of insanity, on Thursdays, at 2.30 p.m., commencing on April 6th. Inquiries regarding the courses should be addressed to the Director of the Pathological Laboratory, Maudsley Hospital, Denmark Hill, S.E.5.

"FROM GRAVE TO GAY."

THE house the General Medical Council owned and occupied so long at 293, Oxford Street, close to Harewood Place, where Sir James Paget lived and practised, was given up at the end of 1915, when the new premises in Halam Street, not far away, were taken into use; it was shortly afterwards pulled down, and the site, which went back to Hanover Square, has been vacant and an eyesore ever since. Huge plaecards now announce that on it will presently be erected the "world's largest super-cinema," with place for 10,000 people, a ballroom, concert hall, and winter garden. The old building, familiar to many generations of the newly qualified; who went there with mingled pride and reluctance—pride at having achieved the right to register, and reluctance at having to part with five pounds for the privilege—was originally built for the Royal College of Chemistry. It was designed in a mid-Victorian imitation of the Italian Renaissance style; it had come to be dwarfed by its neighbours, and both in appearance and purpose seemed wholly out of place amid the drapery emporiums and hat establishments of one of the most frequented stretches of one of the busiest shopping streets of London.

AN OPERATION CIRCLE IN LONDON.

IN 1913 a scheme was inaugurated to promote the interchange of visits of the surgical staffs of certain of the London hospitals. During the war the plan was naturally in abeyance, but at a recent meeting of the representatives of the various hospitals concerned it was decided to restart the circle formed by those hospitals which have not undergraduate medical schools, and Mr. Herbert J. Paterson was asked to act as honorary secretary as before the war. The first operation afternoon will be held at the London Temperance Hospital, at 1.30 p.m., on Thursday, March 30th.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

Cruelty to Animals Bill.

THE bill entitled Cruelty to Animals Bill, which was introduced in the House of Lords on March 7th by Lord Lambourne, has now been printed. The memorandum states that the object is to carry out the recommendations made by the Royal Commission on Vivisection and embodied in their report of March, 1912, including those contained in the reservation memorandum signed by Colonel Lockwood (now Lord Lambourne), Sir William Collins, and Dr. Wilson. There are eighteen clauses and a schedule:

Clause 1 lays down that no person shall perform, on a living animal, any experiment except under the restrictions imposed by the bill.

Clause 2 sets forth the restrictions:

(a) That the experiment must be performed with a view to the advancement by new discovery of (1) physiological knowledge, or (2) knowledge useful for saving or prolonging life or alleviating suffering.

(b) That the experiment may be made only under licence from the Secretary of State.

(c) That the animal must during the whole of the experiment be under the influence of an anaesthetic.

(d) The animal must be killed while under the influence of the anaesthetic.

(e) The experiment shall not be performed to illustrate lectures in medical schools, hospitals or elsewhere.

(f) It must not be performed for the purpose of obtaining manual skill.

(g) The substance known as urari, or curare, shall not be used. And

(h) An inspector shall be present throughout the experiment.

The section is not to apply to an animal whose brain has been completely destroyed; but if this operation be performed by way of an experiment on any animal it shall be conducted in accordance with the provisions of the section so far as applicable.

Clause 3 enjoin that where pain supervenes on an experiment not calculated to give pain initially the restrictions already mentioned shall apply, except that it shall not be obligatory to give an anaesthetic for the experiment or to perform it in the presence of an inspector, or to kill the animal until pain occurs. The animal must then be painlessly killed, and it is required that all places where such experiments take place shall be frequently visited by an inspector.

Clause 4 declares that there shall not be applied to the eye of any animal by way of experiment any matter or substance calculated to give pain for the purpose of absorption through the conjunctival membrane or through the cornea.

Clause 5 prohibits the public exhibition of painful experiments.

Clause 6 states the terms of grant of licence for experiments. The Minister may insert a provision that the place is to be registered as he may direct by general or special order. A licence shall not authorize the performance of more than one experiment, or one series of not more than six connected and consecutive experiments. There shall be specified on every licence the nature of the experiment or experiments to be performed, and the time and place shall also be stated. Every licence shall be granted by the Secretary of State on his own personal responsibility, and he shall not delegate the granting to any other person; and in making the grant he shall pay special regard to the applicant's reputation for humaneness. A licence may be revoked or suspended at any time.

Clause 7 enables the Secretary of State to refer applications for licences to an advisory body selected by him from lists of persons nominated by the Royal Society and the Royal Colleges of Physicians and Surgeons in London. In the event of the bill applying to Ireland, the Royal Irish Academy and the Royal Colleges of Physicians and Surgeons in Dublin are to be substituted for the authorities named.

Clause 8 provides that in the appointment of inspectors special regard shall be had to the reputation of the persons in question for humaneness.

Clause 9 allows the powers of granting a licence to be exercised by an order by any judge of the High Court, or in Scotland of the Court of Sessions, in a case where the judge deems it essential for the purposes of justice in a criminal case.

Clause 10 requires reports of experiments to be made, and Clause 11 provides that reports shall be open to inspection by the public.

Clause 12 makes the maximum penalty for an offence against the Act, on summary conviction in the case of a first offender, a fine not exceeding £50, and in the case of a second or subsequent offence, a fine not exceeding £100, or imprisonment for a period not exceeding three months.

Clause 13 permits right of entry to the police to a place where a justice on information on oath has ground for believing that experiments contrary to the Act are being performed.

Clause 14 permits of a prosecution at any time within a period of two years from the time when the matter of complaint arose, provided that the prosecutor deposit £50 as security for costs.

Clause 15 allows of appeal to Quarter Sessions in England. Clause 16 would, on application of the Act to Ireland, construe Secretary of State to mean the Chief Secretary.

Clause 17 deals with definitions. Animal, under this Act, does not include invertebrate animals; anaesthetic means a general anaesthetic of the nature of a respirable drug or gas; experiment includes all processes for obtaining serums or vaccines for commercial or other purposes.

Clause 18 would repeal the Cruelty to Animals Act, 1876.

The Cost of Medical Benefit.

In reply to Colonel Bann on March 15th, Sir A. Mond said he was proposing to introduce at an early date a bill under which the cost of medical benefit hitherto met by a direct Exchequer grant over and above the normal statutory proportion would be transferred to approved societies in respect of the period ending on December 31st, 1923, and would be met out of their accumulated funds, in which were included the surpluses disclosed at the first valuation and not used for the provision of additional benefits. The bill would not entail any changes in the control of medical benefits. Mr. Walter Smith, on March 15th, inquired whether amounts standing to the credit of the National Health Insurance funds investment account could not be used to meet the economies suggested in the Geddes Report rather than that additional demands should be made on individual societies. Sir A. Mond explained that this could not be done.

Sir A. Mond said, in reply to Sir F. Hall on March 14th, that it was not intended to modify in any way the provisions of the subsection of the Insurance Act under which the arrangements for medical benefit in any area had to be made between the Insurance Committee for the area and the medical practitioner in accordance with regulations of the Ministry of Health.

The Army Estimates.

On the motion for going into committee of supply on the Army Estimates, on March 15th, Sir L. Worthington-Evans stated that the net total for next year would be £62,300,000, including £7,000,000 terminal war charges and £3,550,000 for charges arising out of reductions of strength, including compensation to officers and men whose services were prematurely cut short. It would be seen that, subject to the necessary adjustments, the Estimates were reduced by £16,500,000 as against the £20,000,000 recommended by the Geddes Committee, though in point of fact the definite recommendations of that Committee amounted only to £5,500,000. The reductions of strength contemplated would carry correspondingly heavy reductions in administrative services such as the Royal Army Medical Corps, the Dental, Ordnance and Veterinary Corps. When all these cuts had taken place, the establishment of the British troops, exclusive of those upon the Indian establishment, would come down to 152,836 of all ranks, a reduction of 48,000 compared with last year's estimate, and of 20,000 compared with 1914. He was proposing, however, to strengthen the reserve by the special enlistment of key men, and to restart the militia. He had taken in the Estimates £1,000,000 for the latter purpose. The Irish Command would go, and the troops in Northern Ireland would become an Area Command and form part of a British Command. The London District would cease to be a separate Command, its administrative work in future being done by the Eastern Command. Medical and dental services had decreased by 189 officers and 1,909 other ranks. Of these medical officers 180 were serving in garrisons which did not exist before the war. The health of the army continued very good; the number of admissions to hospitals for preventable diseases during the present year had reached a lower level than during any time in the history of the army; in December last it reached the remarkably low figure of 2.5 per thousand. The Dental Corps establishment was not being filled up with regular officers until the department could be sure what establishment was required in present conditions. The number of equipped beds in hospitals in Great Britain had been reduced by 4,000, but owing to conditions in Ireland the hospital beds there had been increased by over 1,000. Steps were being taken by joint action with the Admiralty, the Air Force, and the Ministry of Pensions to concentrate patients where economies could be effected, and so reduce the number of hospitals. In order to bring the general Army Estimates within the totals assigned to them it would be necessary to reduce the cost of the Territorial Army from an expenditure of £7,250,000 provided for in 1920 to £5,600,000. Some of the units contemplated had never been raised, and this saved nearly half a million, but the balance had to be found. The greater part would fall on the Signals, Medical, Veterinary, and Royal Army Service Corps. Twenty general hospitals and seven casualty clearing stations would be disbanded, and each Territorial Division would have one field ambulance instead of two. The divisional trains and the casualty divisional trains of the Royal Army Service Corps would be organized on a mechanical transport basis, which would afford a considerable reduction in personnel. A part would be obtained by lessening the pay and bounty allowances to officers and men.

The discussion at first turned on an amendment by Lieut.-General Sir Aylmer Hunter-Weston to the question of the possible co-ordination of sea, land, and air forces which he advocated, his motion being that the Government should set up a commission or committee of inquiry into the

subject. Lieut.-Colonel Fremantle, in supporting the proposal, remarked that the recruiting for the medical service, both men and officers, was much the same for all three forces. The supply of medical stores and the provision of hospital ships were similar also. Hitherto the army and navy had each had its hospital ships. What had been said applied still more to the services overseas. There could be a good deal of saving if the officers and men could be interchanged. The naval service as a rule was one particularly for the younger men, and the flying corps also, as regards the medical service, and it would obviously be an advantage if men could be exchanged from one to the other when they had passed the requirements of fitness and agility necessary to the more mobile services.

Sir L. Worthington-Evans, in his reply, referred to a remark by Major-General Seely to the effect that there was an overlapping of chaplains and doctors. That, said the Minister, was a matter which would be looked into at once with a view to economizing. He could not, however, accept Sir Aylmer Hunter-Weston's proposal, as there was not time for the staff to go into questions of this class. The subject, however, did come within the orbit of the Imperial Defence Committee, and he would make representations at once that the feeling of the House was that further steps should be taken in the matter. On this assurance the amendment was by leave withdrawn.

Brigadier-General Colvin, noticing that the field ambulance would be one of the chief sufferers in the proposed reduction, submitted that the Voluntary Aid Detachment might be told off to supply the material for some of these field ambulances.

Lieut.-Colonel Nall (Hullme) regretted the decision to have only one ambulance for a Territorial division. Many men with wide experience believed that three very small cadres for ambulances would be better than the proposed single ambulance. The same number of men could be divided into three instead of being collected into one body. The really serious point in the reduction of the medical establishment arose, however, in the case of the general hospitals. The general hospitals of the Territorial Army did a great work in the war, and in the present vote the proposal was to reduce no fewer than twenty-three hospitals down to three, and to put these on reduced establishment. He suggested that instead of the establishment of ten officers and 100 other ranks in a general hospital it would be sufficient to have five officers—namely, one commanding officer, one registrar, one officer commanding surgical division, one officer commanding medical division, and one quartermaster, with twenty-five or thirty other ranks; one general hospital at least ought to be established in each university town, because it was in the university towns that the best surgical and medical skill could be got. At the present time in these places the Territorial Medical Service had the sympathy of the profession, and it would be a profound pity to cut down these twenty-three hospitals to three—they should be maintained on the basis of one for each divisional area—that was to say, there should be fourteen. Possibly a further reduction could be made, but there should be one cadre for each divisional area.

The motion to go into Committee was then agreed to, and progress afterwards reported.

The Naval and Air Estimates.—Mr. Amery, in introducing the Naval Estimates on March 16th, stated that the total reduction on the net estimates would be £17,595,000, mainly as the result of the Washington Conference. The abolition of the Scottish and Western Approach Commands would save £73,000. The Admiralty ship, and making other reductions the extent, apart from the effects of Atlantic Fleet could not be reduced, but capital ships would be reduced by nearly 16 per cent. below the establishment laid down as the result of war experience. Speaking later on the intended reduction of 20,000 officers and men in the navy, Mr. Amery said they hoped to get rid of a very large proportion of their ratings by ordinary wastage and by stagnation of recruiting. He thought that three-quarters could be dealt with in that way. Mr. Chamberlain afterwards announced that the Government was convinced that it would be a retrograde step to abolish the Air Ministry, but had decided to appoint a Committee or Subcommittee of Imperial Defence to examine carefully the system of naval and air co-operation.

The Schick Test for Diphtheria.—Mr. Mills asked, on March 14th, whether certain medical men in the Ministry of Health were pressing boards of guardians to use a new method of dealing with diphtheria which consisted in testing workhouse children by the Schick test, and inoculating those who reacted; whether qualified doctors disapproved of the composition used in the Schick test; whether the antitoxin employed for immunizing purposes had had fatal results in America; and who was responsible for introducing this process. Sir A. Mond said the answer to the first two parts of the question was in the negative. Information as to the Schick test had been published by the Ministry (BRITISH MEDICAL JOURNAL, December 10th, 1921, p. 994, and February 4th, 1922, p. 203), and a number of local authorities had taken advantage of it, but no attempt had been made to press any to adopt it. He knew it was

said that fatal cases had occurred in Texas, but he was unaware whether this was the cause of the deaths. Accidents were always liable to occur with any form of treatment not properly carried out. He had urged the importance of seeing that when the test was adopted it should be under expert supervision. This method of diagnosis had been before the medical profession since 1913, and had been successfully applied on a large scale in this and other countries. It marked a great advance in methods of prevention and control of diphtheria. On a further question by Colonel Wengwood, on March 15th, Sir A. Mond said that at a conference held in his department a promise was made that it should bear a portion of the cost in a limited number of cases in which local authorities desired to use the test and wanted to secure reliable material. Mr. Gilbert asked whether children attending the Norwood schools of the Lambeth Board of Guardians had been subjected to the treatment without the consent of the guardians. Sir A. Mond said he understood that in the presence of an outbreak of diphtheria in these schools the medical officer thought it necessary to ascertain, by the application of the Schick test, the extent to which the children were liable to infection, and this was done as a measure of urgency without the consent of the Board of Guardians. Mr. Ammon asked whether the helpless children of the poor were being used to experiment upon. Sir A. Mond replied emphatically it was no more a question of experiment than if Mr. Ammon went to his doctor and got a prescription. It was a question of applying an approved method of diagnosis for a very serious outbreak of diphtheria, a method which had proved of infinite value in other countries and in this country where it had been tried by the medical officer of health.

Assessment of Pensions.—Major Tryon stated, in answer to Mr. Mond, on March 16th, that during the last year the number of pensions made permanent as the result of reassessment was 13,500. Of the cases reassessed 76,000 were raised, 441,000 not altered, and 349,000 lowered. The general reduction in average assessment was 4.4 per cent., and was due mainly to improvement in the condition of men suffering from minor disabilities. In reply to Mr. J. Gnest, on the same day, Major Tryon said that every decision on entitlement to pension represented the result of consideration by at least two specially selected officers, one of whom was a medical man. Cases presenting features of doubt or difficulty were submitted to headquarters for consideration by the Director-General of Awards; the latter occasionally availed himself of the technical knowledge of Lieut.-Colonel Rondell, M.P. for Skipton, but he was in no sense responsible for any decision reached. If a man were not satisfied with the decision he could appeal to the independent appeals tribunal, and instructions were given that every assistance should be afforded him. The Pensions Department in the first instance considered his case again because fresh evidence he might submit might enable the department to grant what he asked, and if it did not the appeal went on without prejudice. On further inquiry Major Tryon said that during the year ending January 31st, 1922, approximately 72,500 first applications for disablement pensions had been dealt with, and in about 17,500 of these cases entitlement was not admitted.

London University Site.—Mr. Young, in reply to Mr. Gilbert, on March 16th, said that the Bloomsbury site for the London University still remained in the possession of the Government, and was being administered by the Office of Works. A part of the site was, however, occupied by the University of London on a subtenancy from the Y.M.C.A., and the University had erected thereon with the consent of the Government an Institute of Historical Research. The Senate of the University, in accepting the Government's offer of the Bloomsbury site stipulated, *inter alia*, that an agreement should be concluded between the Government, the Council of King's College, and the Senate of the University as to the terms of removal of King's College from the Strand to the Bloomsbury site. The Government accepted this condition, but such agreement had not yet been concluded. So far as the Minister was aware, no land had yet been collected by the University for the erection of permanent buildings on the site. On further question by Mr. Gilbert, Mr. Young said the Government had not considered the disposal by public sale of the site in the interests of economy.

Medical Examination of Post Office Clerks.—Lieut.-Colonel Nall asked, on March 15th, whether, seeing that candidates for employment as sorting clerks were, if successful in the special Civil Service examination, required to pay a fee of £2 2s. for medical examination before they could be employed, and this regulation prevented otherwise suitable men being employed, he would inquire further into the matter. Mr. Kellaway said no fee was charged for the medical examination in normal cases, but in any case of doubt or appeal which involved reference to a specialist the Commissioners might require a candidate to pay £2 2s. The number of such cases was small.

Answers in Brief.

Since the beginning of 1921 the Board of Education have been obliged by financial considerations to suspend approval of proposals for the provision of twenty-eight open-air schools and nineteen schools for mentally defective children.

The composition of the committee to consider the amalgamation of the medical services of the Navy, Army, and Air Force has not yet been settled.

Sir A. Mond has stated that the Ministry of Health has laid it down that information relating to insured persons which is furnished to the provision of approved societies in the course of their administration of compulsory insurance should not as a general rule be used otherwise than for the purposes of such administration, except with the consent of the insured persons themselves. An exception to this general rule might, however, be made in special cases, where the department informed the society that it was necessary in the interests of justice in criminal proceedings that the information should be supplied.

DISCUSSION IN THE MEDICO-LEGAL SOCIETY.

Opening Remarks by Lord Dawson.

Lord Dawson believed that public opinion was emphatically in favour of some measure of privilege. Within the profession the demand for a measure of protection was wellnigh unanimous. As a profession they had never accepted as just the unlimited right of the courts to enforce disclosure, and they resented the arrogant way in which those rights were sometimes demanded. Their traditions in this respect were deep-rooted, and went back for more than two thousand years to the Hippocratic oath. Certain confidences were given to them which no power this side of the grave would make them disclose. Far better that the ends of justice should be defeated now and then than that the ear of the sick should be prejudiced always. (Applause.) At the same time he admitted that any privilege as between doctor and patient needed to be carefully defined as to its extent. Doctors did not forget their duties as citizens. His proposition was only that a measure of privilege should be granted to doctors in the interests of their patients over and above what was granted to a lay witness. The boundaries of that privilege could best be delimited at a round table conference between doctors and lawyers after the principle itself had been conceded. Without doubt there should be limits to the doctor's obligation to secrecy. When a doctor, in his professional relationship, learned that a cruel wrong was going to be inflicted on an innocent party, he should in no way be compelled to observe his obligation to silence. He should first urge his patient to put himself right and save the innocent party, but he should also give him due notice that if he failed to do this he (the

doctor) would do it for him. The vindication of the law was not on the same plane as the vindication of the individual. There were higher considerations than the furtherance of legal process which claimed the doctor's allegiance, and in this respect he was in the same position as the priest. If a doctor learned that a crime was about to be committed it was his duty to give information to the public authority. If, on the other hand, a crime had been already committed, it was a matter for discussion under what circumstances it was the doctor's duty to inform the authority. If a doctor found that an abortion had been performed, his own inclination was to say that the doctor should not tell the police, because he could not do this without inculcating his patient, and he was bound to protect that individual who had come to him in a confidential relation. Perhaps the difficulties might be met by limiting privilege to civil cases alone; he did not like that line of demarcation, but it might be the most practicable. Other conditions to be observed were that protection or privilege could be ended with the consent of the patient; that privilege might properly be waived when the patient was under 16 years of age or in a case of insanity; that no obligation to secrecy should extend to medical men in their capacity as skilled witnesses; and in cases of malpraxis and charges against a doctor involving his professional relationship, the obligation to secrecy might with propriety be set aside. In what doctors considered as a sacred trust they were not unmindful of their duties as citizens, and he appealed to members of the legal profession to understand the force of their plea and give them support. (Applause.)

Discussion.

Earl Russell said that he had been interested in Lord Dawson's proposals for the working basis on which privilege might be granted. He appeared almost, but not entirely, to have thrown overboard the claim for privilege of doctors in relation to criminal proceedings. Under the law as it stood at present, if a doctor knew of a felony and did not give information about it, he was guilty of an offence for which he might be imprisoned. The speaker supposed a case in which some armed people had made an attack on a post office, and had escaped, but it was known that one of them had been wounded by a bullet in the thigh. Did Lord Dawson seriously claim that if, immediately after this occurred, a doctor was called upon to treat a person, apparently of the criminal class, who had been mysteriously wounded by a bullet in the thigh, he was to conceal the fact from the authorities because it was a case of a crime which had been accomplished, and not of a crime which was contemplated? An example of a civil case was that of a person who had had an accident and made a claim upon the insurance company, who contested the claim on the ground that it was exaggerated. Would it be altogether fair that the insurance company should be debarred from putting into the witness-box the doctor who treated that man immediately after that accident, who could speak as to the injuries the man had actually suffered, especially when this was the only evidence available or the best evidence? He wished to remind Lord Dawson that if a doctor had observed his Hippocratic oath—to which he took no objection, though he did not know that it referred to legal proceedings—and had been discreet in his general conversation, it would not be known that any revelations had been made to him, and there would be no one who would take him into court and ask him these questions. Counsel did not in practice call a witness who was *prima facie* a friend of the other side, especially if they did not know what he was going to say. He also pointed out that if protection was extended to doctors it must be extended to nurses, who frequently heard secrets disclosed in delirium, and similarly to relatives who, even more than the doctor, were the recipients of confidences. Lord Dawson, in speaking of the priest, had appeared to refer to all ministers of religion, but such a thing as the seal of confession was not recognized in any church except the Roman Catholic, and if one were to regard communications made to every minister of religion as privileged this would reach very far, and would have to be extended to Salvation Army captains, who probably received more confidences about criminal matters than any of them. As for Roman Catholic priests, why were they not compelled to disclose? Simply because everybody knew that the Roman Catholic priest would go to prison and stay there rather than break one of the rules of his church. To establish his privilege the doctor must be prepared to take the same risk and invite the judge to commit him. He thought it rather

a dangerous rule, even in civil cases, to give absolute and unqualified privilege to medical men. Medical men were a large class of the community, and not all of them were actuated by the high ideals of the members of that Society. There were medical men who engaged in practices which their colleagues reprobated, and for which when discovered their governing bodies put them under penal discipline. It would be very dangerous to give a wide protection to medical men; far better leave the matter to the discretion of the judge. He thought, however, that some privilege might be given in the case of the director of a venereal clinic; here it was the question of the balance of public advantage, and he believed that the treatment of venereal disease was far more important than the obligation to give evidence about it afterwards. Possibly other cases might belong to the same order, but, generally speaking, he thought it would be a departure of much gravity lightly to accede to any demand for unqualified privilege.

Sir Joun Goodwin (Director-General of Army Medical Services) said that in his department the question arose constantly in connexion with discharged soldiers who were seeking civil positions, and whose previous medical history was asked for. When a soldier was discharged as physically unfit, nothing was put on his discharge certificate as to his physical disability, unless it was due to wounds or injuries in war, which, so far from precluding him from getting employment, rather assisted him. It was always entered on the certificate, when it could be conscientiously done, that though discharged on account of medical unfitness for army service, the man was fit for employment in civil life. Government departments offered a considerable proportion of their posts to ex-service men on the understanding that his department assisted them in deciding as to the man's physical and mental fitness. The medical history sheet was given in confidence to the medical officer of the department which was considering the candidate. A stringent rule was made that no abstracts or copies of medical history sheets were to be taken by other than medical men. Occasionally his department was asked for information in divorce cases. Such information was refused. His department declined to give the previous history of an officer or man as regards venereal disease, but if it was requested to do so it furnished the name of the medical officer who attended the case, and it was then open to the legal authorities to subpoena him. This medical officer was furnished with copies of his own notes on the case. In serious criminal cases, such as murder and manslaughter, copies of medical documents were furnished both to the defence and the prosecution if requested. Another obvious exception to the rule of secrecy was that, of course, copies of case sheets were forwarded to medical men who asked for them because they were continuing to treat the case. The speaker confessed that he could hardly exaggerate the number and the difficulty of the cases that constantly arose.

Lord Russell, who spoke neither as a lawyer nor a doctor, said that he had come to the meeting as a strong adherent of Lord Dawson, and having heard what he had said, he had altered his own opinion entirely! (Laughter.) He thought that what Lord Dawson had had to say about civil cases was extraordinarily nebulous. Any proposals such as Lord Dawson had made, when reduced into the exact terms of an Act of Parliament, would prove absolutely unworkable. Lord Dawson had made a violent attack upon the lawyers, but at all events lawyers were precise thinkers and they understood how necessary it was to lay down regulations, as distinct from general principles; in words which would not admit of too wide an interpretation. He could see no such regulations issuing from what Lord Dawson had put before them. The privilege of lawyers was due to the fact that it was necessary for clients to consult them when about to engage or be engaged in litigation. The doctor was on another basis altogether: he was a witness as to facts, not merely as to statements which had been made to him in connexion with the case. He thought that the whole matter was capable of a fairly simple solution. Most of them in their daily lives, whether professionally or otherwise, found it necessary to forget a good many things, and if a doctor was told certain matters he would, if he were a decent professional man, have forgotten all about them before any question arose publicly. (Laughter.) He was sure that such a little lapse would not be visited with penalty on the day of judgement.

The discussion was adjourned until March 28th.

had the committee not found it necessary to lay violent hands, as the Lord Mayor expressed it, on £10,400 received as legacies in order to meet the expenditure. This is the jubilee year of the hospital, which was opened in 1872 by Prince Arthur, Duke of Connaught, when the late Queen Victoria graciously granted permission to prefix the title "Royal." A special appeal to the public will be made on the occasion of the jubilee. The treasurer, Mr. Lyon H. Maxwell, drew attention to the melancholy fact that the list of subscribers barely contained 1,000 names, and many of these were those of grateful patients. The almoner system last year brought in £1,700.

The Northern Hospital's balance sheet for the past year shows a deficit of £3,000. The chairman, Mr. W. H. Onlton, presented an excellent report of the work done in all departments, and made a powerful appeal to the community to help it to carry on efficiently its beneficent work. As chairman of the Joint Committee appointed in accordance with the proposal of Lord Cave's Committee, he expressed the hope that the voluntary hospitals being comrades in misfortune would in combination weather their difficulties and attain salvation by securing permanent financial support from all classes of the public which had derived in the past such signal benefit from these institutions. It was of the highest importance that employers should call the attention of their employees to the parlous condition in which the voluntary hospitals were. The Hospital Saturday and Hospital Sunday Funds should be largely increased. The contributions from these funds amounted only to about one-tenth of the total expenditure of the hospital. The contributions through the almoner's department recently instituted looked like providing the hospital with £500 a year.

THE LEEDS WORKPEOPLE'S HOSPITAL FUND.

The work of this fund, to which reference has been from time to time made in these columns, continues to be carried on with enthusiasm and success. It is indeed greatly to the credit of the various committees that, despite the sad amount of unemployment that prevails in the city, the main source of income—that, namely, which is derived from the weekly subscriptions of the employees in the different workshops of the city—showed a diminution of only £2,752, the figure for the year ending December 31st, 1921, being no less than £25,853. Other sources of income included collections in public houses bringing in £5,798, club collections £1,345, the annual hospital gala £1,132, and various smaller sources £1,707. The grants made to the medical charities of the city were as follows: General Infirmary £18,000, Leeds Public Dispensary £2,500, Hospital for Women and Children £2,500, Maternity Hospital £900, District Nursing Association £700, Jewish Hospital £200, and smaller sums, including a donation of 100 guineas, towards the Lord Mayor's Fund for the provision of a Princess Mary memorial ward at the General Infirmary. The other activities of the Committee of Management of the fund include the maintenance of three convalescent homes for the use of those who are subscribers; these have been much appreciated during the year, and the number of subscribers who have been accommodated at these homes was 1,372 during the year 1921.

Scotland.

THE OUTLOOK IN PREVENTIVE MEDICINE.

SIR LESLIE MACKENZIE, medical member of the Scottish Board of Health, delivered a lecture in Edinburgh on March 6th on the subject of the outlook in preventive medicine. He said that the new objective in preventive medicine was the production of fitness. The work of the last generation was concerned mainly with the improvement of the environment and the prevention of infectious disease. This work was of supreme importance in the community; but it was animated by the intention to make the environment better fitted to the individual and to fortify the individual against an unwholesome environment. The principal thesis of the lecturer was the standardization of fitness and the methods of testing fitness. Reference was made to the conclusions of the report prepared by Sir James Galloway and his Committee for the Ministry of National Service and on the physical examination of men of military age. He characterized it as the saddest blue book issued in his lifetime, and recommended the careful study of it by all concerned with the production of fitness. He showed a series of slides, specially

prepared for the lecture by Sir James Mackenzie at the St. Andrews Medical Research Institute; the series of heart tracings indicated the type of work undertaken by that institute in the field of heart disease. He emphasized also the importance of the maintenance of sanity, the need for research in many fields, and stated that from the administrative standpoint the difference between the preventive medicine of to-day and that of thirty years ago was that now greater facilities were given for enabling parents and patients generally to discover when they were suffering from disease, and for bringing young children to the welfare centres with a view not to curing sickness but to maintaining health.

GLASGOW MEDICAL LUNCH CLUB.

At the last weekly meeting of this club the guest of honour was the Rev. H. S. McClelland, of Trinity Church, Glasgow, who after lunch related his experiences of the underworld of London, gained by a short stay there disguised as a tramp. Thereafter he gave a racy account of a journey to Palestine and his experiences there. He held the close attention of the members throughout, and was warmly thanked for his most instructive and interesting address. This variation from the usual medical topics was welcomed by the members as one which should be repeated at regular intervals.

Ireland.

ULSTER MEDICAL SOCIETY.

THE annual public health meeting of the Ulster Medical Society took the form this year of a discussion on the Education Act and public health. The president, Dr. Robert Hall, was in the chair, and Dr. H. S. Morrison, M.P., opened the discussion by proposing a resolution advocating the instruction of school teachers in elementary hygiene with the ulterior object of their giving reasonable instruction to their pupils; he thought that much could be done to prevent diseases, such as tuberculosis, in the future by training children, and urged that abnormal conditions of eyes, ears, throat, and teeth required especial attention. Mr. R. J. Johnstone, M.P., said that the Health Committee lately appointed by the medical societies had considered this question very thoroughly; he proposed as an amendment or modification of Dr. Morrison's resolution the conclusions to which the Health Committee had arrived under three headings:

1. That medical inspection of children attending elementary schools under the educational authority of Northern Ireland should be mandatory.
2. That schemes dealing with special defects found by the medical inspection should be initiated on lines laid down in the memorandum of the Local Government Board, 1923, modified to suit local requirements.
3. That provision should be made for the education of physically and mentally defective children.

He urged the meeting to pass strong resolutions and press them not only on the Ministry, but also on the public.

The discussion was continued by Dr. J. Campbell, Dr. Trimble, who entered a special plea for the "defective" school, Dr. St. George, Dr. Gardner Robb, who urged the necessity of the order being "mandatory," Mr. Anderson, Dr. Gillespie, Dr. Leslie, Dr. Calwell, who drew attention to the very large number of existing schools that violated every hygienic principle, Professor Wilson, Dr. Charlotte Warner, who advocated the employment of trained school nurses, and Dr. Reuntol.

The discussion was ended by Professor Lindsay, who said that he believed Ireland to be the only country still without medical inspection of children; he urged the necessity of bringing it to a decent level, and he gave statistics of the results of medical inspection elsewhere.

Dr. Morrison replied, and a resolution embracing both his proposals and Mr. Johnstone's modifications was unanimously adopted by the meeting, and copies ordered to be sent to the Prime Minister, to the Ministry of Education, Ministry of Home Affairs, and to the Departmental Committee of Education, all of Northern Ireland.

GENERAL NURSING COUNCIL.

The half-yearly meeting of the General Nursing Council for Ireland was held on March 9th at 33, St. Stephen's Green.

Sir Edward Coey Bigger, M.D., presided, and there were present: Sir A. Chance, Sir Wm. Taylor, Professor R. J.

Johnstone, Dr. P. T. O'Sullivan, Miss Curtin, Miss Bostock, Miss Walsh, Miss O'Flynn, Mrs. Blundon, Miss Huxley, Miss Reeves, Miss Michie, and Mr. W. O. R. Reidy, Registrar. An apology for non-attendance was received from the Countess of Kenmare.

The reports of the Rules, Finance, and Registration Committees were submitted to the Council and formally adopted.

The proposed establishment of a General Nursing Council for Northern Ireland was discussed by the Council, and the following resolution was unanimously passed, on the proposition of Sir Edward Coey Bigger, seconded by Professor R. J. Johnstone, M.P.:

That the General Nursing Council for Ireland consider that the setting up of a separate council for Northern Ireland will seriously interfere with the interests of nurses; that the keeping of two separate sets of registers in this country will occasion much extra trouble for nurses who may be desirous of acting throughout the entire country and will mean that practice by all nurses resident close to the boundaries will in all probability be penalized by having to pay double fees; that on the original passing of Nurses Registration Acts it was only intended that there should be three Nursing Councils for Great Britain and Ireland and that the setting up of an extra council will be confining to nurses in England, Scotland, and Wales; and, lastly, that a fully representative meeting of nurses in Belfast has already formally protested against the establishment of a Nursing Council for Northern Ireland.

We therefore believe that the proposed change in the present system of registration of nurses would be against the best interests of all classes of nurses in Ireland.

The Registrar was directed to forward copies of this resolution to the heads of Governments in Ireland. After the transaction of some further business, the meeting adjourned.

Correspondence.

ROUTINE PELVIMETRY IN ANTE-NATAL CASES.

SIR,—At a recent meeting of general practitioners the subject of routine pelvimetry in pregnant women was raised, and I was surprised to find that only two of those present adopted pelvimetry as a routine practice. After nearly a quarter of a century in general practice I cannot help comparing the distressing and anxious forceps cases of former years with my experience since I adopted routine pelvimetry. I am not writing this letter for gynaecological specialists, but to call the attention of my fellow general practitioners to the great advantage of routine pelvimetry in all cases of pregnancy. My practice is to rely principally on the measurement of the external conjugate; if under seven inches I watch the ease during the last month of pregnancy, and as soon as the foetal head appears to fit tightly into the pelvis I induce labour by inserting a small rubber bag about the size of a cricket ball. However advisable and necessary the use of forceps may be at times there is no doubt that their habitual employment is a barbarous practice.

The advantages of induction in suitable cases are:

1. The risk to mother and child is less than in a difficult forceps delivery.
2. The memory of the confinement is not a nightmare to the mother, as so often is the case in a bad forceps delivery.
3. The practitioner can choose his own time, with all its advantages of aseptic preparations.
4. If properly managed an induction is as free from risk as a normal confinement.

I believe that routine pelvimetry is now taught at all the principal medical schools, but from my own experience among practitioners of some years' standing I know that it is the exception. I hope that this letter will convince them of its advantages, both to their patients and themselves.—I am, etc.,

R. THORNE THORNE.

Woking, March 23th.

THE TOXAEMIAS OF PREGNANCY.

SIR,—In her excellent address (March 4th, p. 335) Professor Louise Mellroy endorses the toxæmic origin of the toxæmias of pregnancy, and presents the argument of those who believe in this hypothesis in all its apparent strength, but with its weaknesses still there. This argument, I submit, is fallacious; the conclusion, not only not proven, but improbable, and even erroneous. The argument, as I understand it, is this: Because with the advent of pregnancy certain changes take place in distant organs—in the breasts and endocrine glands—due to something getting into the blood from the living ovum, which

acts on these distant parts, the toxæmias of pregnancy—which only occur in pregnancy, and are not to be explained in any other way—are also due to this something. This something is called an enzyme or ferment. Besides being beneficial (causing the breasts to develop) it is also toxic (causing necrosis of kidney and liver cells). Under normal conditions the toxic element is prevented from becoming operative because antibodies simultaneously arise which neutralize it. "In this way auto-intoxication is prevented, and the woman is immunized by her own serum."

Apart from the fact that certain toxæmias of pregnancy occur in the absence of pregnancy (for example, acute yellow atrophy), and apart from many other arguments not here adduced, one wonders why a ferment developed by the ovum in the normal should be toxic. The only admissible evidence I can think of warranting the assumption that the enzyme at its source is toxic, is that the syncytium erodes the endometrium; and even this is questionable, since such erosion is a *sine qua non* of the continued existence and development of the ovum. It is a natural, beneficial change, and not a process toxic to the host as an individual. To suppose from this that the enzyme entering the blood stream may also cause necrosis of kidney and liver cells, unless neutralized by antibodies, is, I think, rather a jump—and a jump in the dark. For if the enzyme is one enzyme, and not only causes the embedding of the embryo but also the changes in the breasts and other parts, and if in the normal antibodies arise neutralizing it, one wonders how it is that in such case the syncytium goes on growing and the breasts developing. To get over this difficulty we must posit at least two enzymes—the one beneficial and the other toxic—but only one antibody neutralizing in normal cases the toxic part. But whilst the assumption of a beneficial enzyme is justified by everything, the assumption of a toxic enzyme and its antibody in normal cases are only justified by the inability of obstetricians to explain in any other way the rise of the maternal visceral lesions in the toxæmia of pregnancy.

The discovery of emboli formed of syncytial fragments and villi in the lungs of women dead of eclampsia does not justify it. I believe I am right in stating that Schmorl found such fragments in the bodies of pregnant women dead from other causes than eclampsia or the toxæmia of pregnancy. And the fact that syncytial masses are wide spread in chorion-epithelioma shows beyond everything that similar fragments in pregnancy do not produce a toxin causing the toxæmia of pregnancy or eclampsia; for in chorion-epithelioma no such condition as the toxæmia of pregnancy arises. Malignant disease does not produce such a toxæmia, unless it directly affects the visceral organs concerned in dealing with the products of metabolism—a point which in this question has not been considered by the adherents of the toxæmic origin of eclampsia. Moreover, if a toxin arises from the syncytium, this should be more active in the early months of pregnancy. But the toxæmia of pregnancy is a late manifestation. This argument against the toxæmic theory is also turned aside. Since the severe toxæmias of pregnancy, "such as are found in eclampsia and accidental hæmorrhage, occur in the late months of pregnancy," Professor Mellroy argues that it is "open to question" that the syncytial poisons are most active in the early months. I submit she should have argued that it is open to question whether they are poisons at all.

This evidence, clearly, is in line with that afforded by chorion-epithelioma; with the fact that placental changes often occur apart from and in the absence of any toxæmia of pregnancy—that the toxæmia of pregnancy does not occur in carneous mole, in retained placenta, and in many other conditions in which it ought to occur if a toxæmic origin of the disease exists. So also the association of accidental hæmorrhage with eclampsia or the toxæmia of pregnancy is no evidence of a toxæmic origin. It is just the reverse. It is evidence of the mechanical cause of the maternal visceral lesions which lead to these metabolic aberrations. Young¹ himself has cited cases in which albumin was not present in the urine when the uterus had already become distended with blood, the result of concealed accidental hæmorrhage. Albumin only showed itself after some hours had elapsed. It is not surprising that in many cases of 'accidental' hæmorrhage associated with eclampsia that albumin should be found in the urine before the occurrence of the bleeding. Albuminuria is not uncommon in pregnancy;

¹ Further Observations on the Etiology of Eclampsia and the Pre-eclamptic State. *Proc. Roy. Soc. Med., Obstet. and Gyn. Sec.*, 1922, vol. xiv, p. 24.

on the contrary, it occurs so frequently that it has been regarded as incidental to pregnancy—to be expected, not to be regarded with surprise.

The evidence, such as we have, of the toxæmia of pregnancy and of eclampsia points to the underlying condition being a disorder of general metabolism, and Professor Mellroy, in her paper, not only advances evidence that this is so, but advances no evidence to show it is otherwise. Thus we find the statement: "It is difficult to distinguish a toxæmia of pregnancy in a previously healthy individual from that of a pregnancy superadded to an already existing disease." If the toxæmia of pregnancy is a specific condition, such difficulty surely should not occur. All the changes in the urine and in the blood found in the toxæmia of pregnancy are adequately explained by the lesions of the liver and of the kidneys which we know exist in the toxæmia of pregnancy. Professor Mellroy herself states that "It is essential to examine the blood in order to determine the amount of retention of the various products of disordered metabolism." And all her treatment is directed to the elimination of these natural poisons (natural waste products), or to the staying of the fits, which their accumulation causes (morphine, etc.). With such evidence as this it is not necessary to adduce an unknown, an undisputed, a purely hypothetical, toxin, and in the normal its antibody. The visceral lesions in the toxæmia of pregnancy and in eclampsia can be otherwise explained; and their existence explains all else in these conditions. I recently showed one remarkable factor associated with eclampsia²—its occurrence in women in whom there is reason to believe the pressure within the abdomen is higher than usual in pregnancy, indicating a physical cause. The incidence of eclampsia shows this at every obstetrician, but nearly all turn a deaf ear. Yet we read that "the main work of the future lies in the investigation of the toxæmia of pregnancy." Does not the incidence of eclampsia indicate the incidence of the toxæmia of pregnancy, and its cause, the cause of the lesser, the preceding condition? In spite of the difficulties and doubts, and in spite of the urgent necessity of explaining eclampsia, the "toxæmic origin of eclampsia is now accepted." That is the trouble. Although "at present we only stand on the threshold of the subject and contemplate as if in a mist the difficulties and complications which confront us," observers and teachers of obstetrics have made up their minds. They are not uncertain—they are quite sure! Had they better not beware of the ditch, lest, being befogged (as they themselves admit), they lead unsuspecting people, instead of to the light, into the abyss?—I am, etc.,

London, W., March 5th.

R. H. PARAMORE, F.R.C.S.Eng.

QUACKERY IN RELATION TO DISEASES OF THE EYE.

SIR,—The interesting short article on quack "oculists" in your issue of March 18th, p. 446, reminded me of Samuel Pepys's naive surprise which he expressed under date July 3rd, 1668:

"To an alchouse: met Mr. Pierce the surgeon, and Dr. Clerke, Waldron, Turberville my physician for the eyes, and Lowre, to dissect several eyes of sheep and oxen, with great pleasure and to my great information. But strange that this Turberville should be so great a man, and yet to this day had seen no eyes dissected, or but once, but desired this Dr. Lowre to give him the opportunity to see him dissect some."

It is surprising that this discovery aroused no misgivings in Pepys's shrewd mind; perhaps the entry under June 23rd of the same year may explain, to some extent, his unshaken confidence:

"To Dr. Turberville about my eyes: whom I met with: and he did discourse, I thought, learnedly about them: and takes time, before he did prescribe me any thing, to think of it."

Even in the twentieth century it is useful, when we are ignorant, to be able to talk learnedly and to appear to reserve judgement on a case until we have had the opportunity of private thought concerning it, unless, perhaps, in cases when our knowledge of human nature tells us that a slapdash diagnosis is expected; even here the learned talk is an elegant trimming.—I am, etc.,

Falkirk, March 18th.

GEORGE CLARK STEWART.

² "Eclampsia and its Incidence," *Lancet*, 1921, ii, p. 1147.

THE RECOGNITION OF AORTIC INCOMPETENCE.

SIR,—The importance of the subject must be my excuse for again troubling you. It seems to me that the difference between Dr. Brockbank and myself is one of prospective or proportion rather than fact. As the reason for Dr. Brockbank's article was the prevalence of faulty diagnosis I still think that the proportionate value of the signs is most important in teaching, otherwise if the student attaches equal importance to very rare conditions and common conditions he will have no sure light for guidance. A systolic murmur in the second right space is quite common in healthy persons; on the other hand, stenosis of the aortic valves without regurgitation is so rare that I still think the student should be taught to resist the temptation to diagnose stenosis in the absence of a diastolic murmur. I do not mean to assert that stenosis does not occur without a diastolic bruit, but the occasions are rare.

In the same way I think the student should be taught to attach great importance to the visible signs of aortic regurgitation, for they are present in many cases before the apex is much displaced outwards.

As regards aortic stenosis I think Dr. Brockbank, on consideration, will agree with me that we have both laid ourselves open to criticism in omitting all mention of a most important sign—namely, the anacrotic pulse.—I am, etc.,

Liverpool, March 13th.

C. H. BROOMHEAD.

PREVENTION OF VENEREAL DISEASE.

SIR,—Your correspondents Sir Archdall Reid and Sir Bryan Donkin advanced the proposition that, whenever certain methods of prophylaxis were employed, venereal disease was reduced to "vanishing point." We presumed that they had arrived at this conclusion after collecting figures and considering carefully all the factors affecting a venereal disease rate. We asked them to present for judgement by an expert statistician the facts on which they base their claim.

In so far as self-disinfection is concerned, we confess ourselves unimpressed by the data so far published; we think that an independent expert in statistics would judge that, considering the complexity of the factors involved in a statistical change in venereal disease rates, nobody would be justified in drawing such sweeping conclusions as those of your correspondents on the facts they have hitherto presented. We imply no bad faith on the part of those who collected the figures. We are not satisfied that the general rate for Portsmouth in 1917, the year when Sir Archdall Reid commenced his campaign, was 92. The rate of 92 was stated in the White Paper issued by the Ministry of Health to be inaccurate, like all rates for Portsmouth given in the same table for 1916 and after. It appears from the explanation in the White Paper to have been calculated on the same basis as resulted in a rate of 163 for Portsmouth in 1919. In any case it is not comparable with the rate of 1.5, claimed by Sir Archdall Reid, since the general rate included all cases, relapses, imported and fresh cases, while the rate of 1.5 appears to have been arrived at by excluding all cases where the patient stated on cross examination that he contracted the disease in some other station.

Admissions to other hospitals for disease contracted in Portsmouth. Of course we assumed that men who reported venereal disease in Portsmouth were admitted there. But men remained in Portsmouth only a short time (we calculated an average of 2.8 months from Sir Archdall Reid's statement that 2,000 men were constantly under his charge for twenty-eight months and 20,000 passed through the barracks).

Syphilis is a disease with a fairly long incubation period and men do not report it by any means as soon as the primary sore appears; gonorrhoea is regarded lightly and is fairly easily concealed; and Sir Archdall Reid used to tell his men that, if they contracted venereal disease after hearing his lecture, it would look as though they were "funking the firing line." We think all of these are factors making for disease contracted in Portsmouth being reported only after leaving the station, and to our knowledge cases of disease contracted at Portsmouth which developed while there and after leaving, were treated by private practitioners in London.

Our reference to the effect of salvarsan on the general rate is quite pertinent, since the general rate published by the army includes syphilitic relapses requiring readmission to hospital, which were considerable in number under mercurial treatment and have been reduced almost to vanishing point by salvarsan treatment.

We are amused to see that in their "score of English boroughs" who, "in scorn of the Ministry of Health," have adopted the teaching of "quick self-disinfection," seven borough and urban district authorities that are not responsible for the provision either of facilities for treatment or of instruction under the Ministry of Health scheme have been included, while in two of the county authorities claimed as supporting the Society for the Prevention of Venereal Disease the medical officers of health are members of the National Council and active supporters of its policy. With regard to the experiences of Sir J. Barrett, our opinions, based on his own writings, are unchanged.

We have carefully been through the evidence given before the Royal Commission. We fail to understand why continual statements are made that the question of prevention was not brought before that body. Evidence was given by several witnesses who were clearly cross-questioned, mainly by present medical members of the National Council. We can trace no questions drawing particular attention to this method of prevention being put by the medical member now known to sympathize with the views of the Society, nor is there any evidence recorded as given by that medical member of the Commission when he himself gave evidence.

We should be glad to know on what evidence the statement is based that "the question of self-disinfection in men had been excluded from the deliberations of the National Council." Anyone who will read through the published annual reports of the National Council from 1917 up to date will find in each report a full account of the discussions on this aspect of the antivenereal problem, showing that full weight and attention had been given by the Council to self-disinfection, and it is in accordance with the evidence laid before them that their present policy has been formulated.

In regard to personal instruction Sir A. Reid writes:

"The orderly would say, 'Party joining station, sir.' Thereupon I would snatch a small bottle of permanganate solution and a swab of cotton-wool, go out . . . and then gabble off my little lecture. The one and only thing I tried to be impressive about was the urgent necessity for speed in disinfection."

He states in another part of his book that this was his procedure if only one man had joined. This we consider personal instruction.

The civilian question is, however, now much more pressing. Sir Archdall Reid says in his book:

"It always seemed to me of the utmost importance that they should understand. It was not sufficient to tell them to do this and that. The reasons had to be explained. . . . Instructions alone are not sufficient. The men must be treated as reasonable beings. They must be told not only what to do but also the reasons for doing it."

Can he reconcile the statements in his book with the instructions by poster only recommended in his letter?

But to come to the point. From the lips of the honorary secretary for the Society for the Prevention of Venereal Disease at a meeting on March 10th, and from the letter of Sir Archdall Reid and Sir Bryan Donkin, we have now got the considered policy of that society. Put shortly it is as follows:

1. No instruction to any boy under 18.
2. No instruction to any woman except prostitutes over 21.
3. Disinfectant outfits (packets) only to be carried by intending fornicators.
4. Instruction to be given by posters in public lavatories (evidently quite different from those which the Derbyshire bill-posters refused to display) so worded as . . . "signer" of 18 obtain and use effectively the "innocent boy" of 17 is warned against scabies and sepsis!

We are very curious to see the draft of such a poster.

Thus all the pronouncements of the president of the Society for the Prevention of Venereal Disease in 1920 and 1921 with regard to "this knowledge" being accessible to boys and girls at the age of puberty, and the more logical demands of Miss Ettie Rout (made when she was a member of the Grand Committee of that society) are thrown overboard, and the utility of what is left must be considered infinitesimal, even by a believer in individual self-disinfection.—We are, etc.,

E. B. TURNER,

Chairman, Medical Committee,
National Council for Combating
Venereal Diseases.

CHARLES GIBBS,

Surgeon to London Lock Hospital
and to Charing Cross Hospital.

London, March 14th.

* We are loth to interrupt a correspondence upon this subject, the importance of which we fully appreciate, but it will not be possible to continue the publication of such lengthy letters as those both sides have addressed to us since

the correspondence was opened by Sir Bryan Donkin and Sir Archdall Reid. We are prepared, of course, to receive any brief correction of matters of fact, but we cannot think that the prolongation of the correspondence will serve any useful purpose, more especially in view of Sir Alfred Mond's statement in the House of Commons on March 13th that he hoped "to get together a body of medical men who would look at this subject from a medical point of view and advise me."

HAEMORRHAGIC COLITIS.

SIR,—I was much interested in Mr. Lockhart-Mummery's comments on my report of two cases of haemorrhagic colitis. When I wrote this I unfortunately was unable to refer to Mr. Mummery's work on *Diseases of the Colon*, but I have now had an opportunity of so doing, and I find the description therein of this condition is exactly that of the two cases of Dr. Mitchell Stevens which I reported. It is evident from Mr. Mummery's letter that the condition is a very rare one.

Regarding the method of closure of colostomies, I appear to have conveyed a different impression from that which I intended. My experience is limited to about a dozen cases, some of which were done by the intraperitoneal method and others by the extraperitoneal. As far as that experience goes it is entirely in agreement with Mr. Lockhart-Mummery regarding the merits of the two procedures. I feel that the former is far the most satisfactory, and is the one I should always adopt in futuro. I closed a colostomy in a somewhat difficult case recently by the intraperitoneal method, which had been made for a stricture of the rectum, and obtained primary union and a very satisfactory result.—I am, etc.,

Cardiff, March 13th.

J. W. GEARY GRANT.

ARTIFICIAL LIMBS.

SIR,—In the report of my demonstration of patients wearing artificial legs, which appeared in the *BRITISH MEDICAL JOURNAL* of March 11th, the following sentence occurs: "On the whole the best artificial legs now made were those of the American Rowley firm." This is incorrect. What I did say, and what has evidently been misunderstood by the reporter, was that at the Roehampton Exhibition of Artificial Limbs in July, 1915, the Rowley firm was awarded the gold medal for artificial legs, and further that the knee-control mechanism introduced by that firm has now been adopted by Government for the "standard limb" which all Government limb makers supply. Other portions of the "standard limb" have been adopted from other limb makers. I trust that you will find room for this correction in justice to the many other excellent limb makers who supply the "standard limb."

While writing I may add that the views attributed to me in the report as to the relative value of different stumps are in several instances incorrect. Those who may wish to know what these views are will find them in an article published in the *Edinburgh Medical Journal*, November, 1920.—I am, etc.,

Edinburgh, March 14th.

CHARLES W. CATHCART.

FATS AND GOITRE.

SIR,—I should like to confirm Dr. C. R. Gibson's observations in your issue of March 11th on the prevalence of goitre in the Northwich and the south-eastern districts of Cheshire. In 1916 the army recruiting board at Warrington examined 2,200 men from these districts, and found 16 cases of goitre, a rate of 7 per 1,000. From Warrington and the Lancashire districts around it 23,300 men were examined and 34 cases of goitre were found, giving a rate of 1.5 per 1,000. These figures tend to show that goitre—simple goitre, for exophthalmic goitre was excluded from these observations—is four times more prevalent in these districts of Cheshire than in a Lancashire district some fifteen miles distant from them. These figures were published in the *Lancet*, 1920, vol. i, p. 909, in a paper on the congenital and hereditary defects in recruits.—I am, etc.,

Warrington, March 12th.

J. S. MASSON.

CLINICAL FORMS OF INFLUENZA.

SIR,—O. Clayton Jones mentions in your current number various forms of influenza occurring during the recent epidemic. Here among the troops we have had very varied experience of very high temperatures with sudden crises and symptomatic pneumonia. Temperatures as high as 104° F.

were present at night, which dropped to 93° F. in the morning, without any other symptoms. Other cases showed all the distress of severe pneumonia, with typical rusty sputum, which cleared up during the next twenty-four hours without any ill result.—I am, etc.,

THOMAS M. KENDALL, B.A., L.R.C.P.

Military Hospital, Parkhurst, I. of W., March 13th.

HOSPITAL POLICY.

SIR.—As you are desirous of this matter being fully discussed by the Divisions, perhaps you will allow me to present certain thoughts for their consideration.

It would be well if we could present a united front at Glasgow. Personally, I have read through the report and find myself in agreement with it, except in regard to II, 6 and 7. These paragraphs simply deal with the socio-political side of the question, about which, however much concerned we may be as private citizens, as an association of medical practitioners we do not seem to be called upon to express an opinion, especially if it cause dissension in the profession.

As an association, it seems to me that we are not so much concerned about how the hospitals are financed, as long as it be done so as to enable us to do the work efficiently. Nor is it a matter of importance to us how the governing bodies are formed as long as the administration does not prevent us doing the work efficiently. Why should we not confine ourselves to the really important things, such as:

1. That the profession is adequately remunerated for work done which cannot be called charity.
2. That there is adequate provision for medical education.
3. That the profession is adequately represented on the governing bodies.
4. That the staffing of hospitals be carried out in a manner fair to all properly qualified medical practitioners.
5. That the general practitioners obtain a proper place in the general hospital organization of the country.
6. That hospitals of all kinds, convalescent homes, ambulance associations, nursing associations, etc., be all linked up in an effective national organization.

Is there not enough work for us to do in the above without being dragged, as a profession, into the quarrel about whether it is better for the nation to finance the national lifeboat service out of the taxes or to let it rely upon the generosity of charitable individuals?—I am, etc.,

Holston, March 20th.

FERDINAND REES, M.D.

PHYSICAL EDUCATION OF GIRLS.

SIR.—A joint committee of men and women representing the medical and teaching professions has been formed to inquire into the present physical education of girls, particularly as to its results, beneficial or harmful, either during girlhood or in later life. The term "physical education" is understood to include athletic sports and games, as well as disciplined exercises.

The committee will be grateful for any information which members of the medical profession may be willing to give as to their experience in this matter. Communications should be addressed to the Honorary Secretary, Joint Committee, College of Preceptors, Bloomsbury Square, W.C.1. All information will be regarded as strictly confidential. A form of questionnaire will be sent if desired.—I am, etc.,

GEORGE F. STILL,

Chairman.

London, March 17th.

SUN OR AIR?

SIR.—Dr. Argyll Campbell and myself are not at variance with Sir Henry Gauvain, as Dr. Devereux, in his kindly letter of appreciation of our work, suggests. We have brought forward the importance of cold, moving air in stimulating the metabolism, and of the evaporative power of cold air on the body, and particularly on the lungs, but we do not question the beneficial effect of sunlight combined with cold air. The time spent recently at the English sanatorium at Montana showed one of us how grateful and stimulating is the combination of Alpine sunshine and cold air.

Sir Henry Gauvain has no doubt that his patients do better in the summer than in the winter, and we do not question his clinical experience. Probably the summer spent in England and the winter in an alpine climate is the best possible combination, and it would be a most interesting experiment if Sir William Treloar could establish a branch hospital at Montana as he has at Hayling Island.—I am, etc.,

London, N.W., March 22th.

LEONARD HILL.

CLAYDEN v. WOOD-HILL.

SIR.—I am enclosing the seventh list of subscriptions to the Wood-Hill Fund, and should be much obliged if you would kindly insert it in your next issue.

A noteworthy feature of this list and of the previous one which was published on March 4th is the large number of contributions from medical societies, honorary staffs of hospitals, Divisions and Branches of the British Medical Association, etc. In the two lists there are no less than seventeen contributions of this type. These contributions have been of material assistance to the Fund, and if similar bodies of medical practitioners in other parts of the country will follow suit the total amount required to reimburse Dr. Wood-Hill (£2,250) will certainly be obtained.—I am, etc.,

HAMILTON A. BALLANCE,
Honorary Treasurer.

All Saints Green, Norwich,
March 18th.

Seventh List of Subscriptions.

Amount previously acknowledged, £1,071 4s. 10d.

Universities and Colleges.

THE CHAIR OF MIDWIFERY AT EDINBURGH.

It is announced that Dr. Benjamin Philip Watson, professor of obstetrics and gynaecology in the University of Toronto, has accepted an invitation from the curators of the University of Edinburgh to become professor of midwifery in the vacancy caused by the resignation of Sir Halliday Croom. Professor Watson will be responsible for the teaching of both midwifery and gynaecology. He is an Edinburgh student, and graduated M.B., Ch.B. with first-class honours in 1902, and M.D. with gold medal in 1905. He is joint author with Dr. Freeland Barbour of a well-known handbook, *Gynaecological Diagnosis and Pathology*. Professor Watson, who was lecturer on midwifery and gynaecology in the School of Medicine of the Royal Colleges, Edinburgh, for one session (1912-13), was appointed to the chair which he now vacates in Toronto in 1913; during the war he served with the Canadian Hospital at Salonica.

UNIVERSITY OF OXFORD.

Radcliffe Travelling Fellowship.—David George Turner Kerr Cross, B.M., St. John's College, has been elected to a Radcliffe Travelling Fellowship.

UNIVERSITY OF LIVERPOOL.

The following candidates have been approved at the examination indicated:

FINAL M.B. AND CH.B.—Part I: J. S. Bradshaw, M. Cohen, W. R. H. Ellis, E. Fisher, D. Flentley, A. B. Griffiths, J. Hallam, G. M. Hughes, G. H. Mann, Phyllis Marsh, T. V. O'Brien, D. U. Owen, R. A. Roberts, Helen Standing, J. G. Thomas, H. Walker, A. E. Wall. **Part II:** J. O. Edwards, R. C. Gabbins, W. D. Jeans, T. Knowles, P. Madan, J. R. Parry.

Diploma in Public Health.—H. T. Hughes, H. E. Marsden, Nellie Wall. **Diploma in Tropical Medicine.**—J. R. Bhatia, E. R. W. Gilmore, A. R. Jennings, S. H. Paul, J. Pinder, Gladys Rutherford, Q. Stewart. **Diploma in Medical Radiology and Electrology.**—J. E. Bannen, A. Y. Fullerton, E. S. Gawne.

*Recommended for the Alan H. Milne medal.

UNIVERSITY OF MANCHESTER.

A Delapine Fellowship.

A Fellowship for research in Preventive Medicine has been established by Dr. Auguste Sheridan Delapine, M.Sc., in the Department of Health and Bacteriology in the University from 1891 to 1921, by the addition of the former Junior Research Fellowships in interest derived from an endowment of £1,000 made by Dr. Charles Slater of Tunbridge Wells. The regulations provide for a Fellowship of £300 to be offered biennially and to be open to competition by candidates who are graduates in medicine of this or any other approved university, or who hold an approved registrable medical qualification.

The following appointments have been made: Lecturer in Ophthalmology, Dr. J. Gray Clegg, F.R.C.S.; Clinical Lecturers in Ophthalmology, Dr. H. H. McNabb and Dr. John Wharton.

ROYAL COLLEGE OF PHYSICIANS OF LONDON.

An extraordinary committee of the Royal College of Physicians of London was held on March 15th, when the President, Sir Norman Moore, was in the chair.

Licences were granted to the following candidates: Ruth W. Plimsoll (Royal Free Hospital), T. A. S. Samuel (London Hospital).

Communications were received from: (1) The Secretary of the Royal College of Surgeons, reporting proceedings of the Council of that College. These were received and entered on the minutes. (2) The executors of the will of the late Lady Clark, dated February 28th, 1922, asking whether the College will accept the bequest of a portrait of the late Sir Andrew Clark, formerly President of the College, by Frank Holl, Esq., R.A. This was received with thanks to the executors.

Reports of the Committee of Management were adopted recommending that the St. Dunstan's College, Catford, should be recognized for instruction in chemistry and physics, and the Boys' Intermediate School, Aberdeen, for instruction in chemistry, physics, and biology.

Recommendations of the General Medical Council.

The following reports were then received:

(a) A recapitulation of the draft rules in respect of examinations for the Diploma in Public Health, proposed by the General Medical Council, and submitted to last College meeting, together with observations which it is suggested that the College should make upon them.

(b) A recapitulation of the draft recommendations in respect of (qualifying) Professional Examinations, propounded by the General Medical Council, and submitted to the last College meeting, together with observations which it is suggested that the College should make upon them.

(c) Provisional new regulations for candidates for the Licence of the College, and the Membership of the Royal College of Surgeons, based on the proposed course of study and examinations which was adopted at the last meeting of the College.

After some discussion, and some minor alterations in the reports, they were adopted.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.

Nominations for Councilors.

Monday last, March 20th, was the latest day for receiving applications from candidates for election on the Council next July. The three retiring candidates—Sir Charles Ballance, Sir William Thorburn, and Mr. W. McAdam Eccles—seek re-election. The other candidates are: Mr. John Herbert Fisher, Fellow 1893, Member 1891 (St. Thomas's, ophthalmic); Dr. Victor Bonney, Fellow 1899, Member 1895 (Middlesex, obstetrics and gynaecology); Mr. R. Pugh Rowlands, O.B.E., Fellow 1901, Member 1896 (Gny's).

Obituary.

DR. EDWIN DENING, who died on March 7th at Stow-on-the-Wold, Gloucestershire, was born at Comcytrowe, Taunton, in 1855, and qualified at University College Hospital in 1877. After an apprenticeship at Tetbury he commenced practice at Stow-on-the-Wold in 1879, and for forty-three years devoted himself unsparingly to the demands of a scattered Cotswold practice, winning the gratitude and love of a large circle of patients. He was the first local medical officer of health under the Urban District Council from 1894 until his death. He was a man of wide sympathies, taking a keen interest in all the affairs of the town, being chairman of the Charity

Board, a keen volunteer, holding a commission as lieutenant in the Stow company, and also a prominent Freemason. During the war he acted as one of the medical staff of the local V.A.D. hospital. He was a very old member of the British Medical Association, and in 1899 he was President of the Oxford Branch.

The death is announced of Dr. JAMES ERSKINE of Glasgow. He was a native of Paisley, and was educated at Glasgow University, where he graduated M.A. in 1877 and M.B., C.M. in 1882; he took the diploma of L.R.F.P.S.Glas. in 1881. He specialized in ear diseases, and had been lecturer on aural surgery at Anderson's College, Glasgow, aural surgeon to the Glasgow Central Dispensary, and assistant surgeon to the Glasgow Hospital and Dispensary for Diseases of the Ear. He took great interest in local affairs, and served several terms on the town council, from which he retired in 1920. For some years he was a member of the Glasgow Parish Council, and chairman of the District Hospitals Committee. He was a member of the Glasgow Central Division of the British Medical Association.

We regret to record the death, after a long and painful illness, of Dr. GEORGE WESTBY, of Liverpool. He was the son of the late Canon Westby, of Dublin, and was born in 1846. He received his medical education in Dublin, taking the diplomas of L.R.C.P.I. and L.R.C.S.I. in 1877; subsequently he took the M.R.C.P.I. in 1881. Dr. Westby took a prominent part in the volunteer movement, and held a commission for 25 years in what is now known as the 6th (Rifle) Battalion, the King's Liverpool Regiment, retiring with the rank of surgeon-lieutenant-colonel; he received the Volunteer Decoration for his services. For over forty years he had an extensive practice in Liverpool, and won the affection of all with whom he came in contact. He was an old member of the British Medical Association, and was also a Freemason.

The death is announced of the Rev. WILLIAM STURDY BRANLEY, rector of Beaworthy, Devon, in his 84th year. Before taking holy orders Dr. Branley had become qualified as a medical practitioner, having taken the diplomas of M.R.C.S. Eng. and L.S.A., and graduating M.D. of St. Andrews. He was ordained deacon in 1872 and priest in 1875 in the diocese of Ripon. After two curacies in Yorkshire he became chaplain to Manchester Workhouse from 1880 till 1908, when he accepted the living of Beaworthy. He is survived by his widow, two sons, and two daughters.

DR. JOHN INNES of Aberdeen died on March 5th in his 53rd year after a long period of ill health. He was a native of Glenlivet, and after some years in business entered Aberdeen University, and graduated M.B., C.M. in 1896. He settled in Aberdeen and rapidly acquired a considerable practice by his devotion to his patients. He was a member of the Aberdeen Division of the British Medical Association, and had held the rank of major in the R.A.M.C.T. Dr. Innes is survived by his widow and two sons, of whom the elder was in partnership with his father.

HARRIS GRAHAM, B.A., M.D., for thirty years professor of pathology and practice of medicine in the American University of Beirut, died in his 60th year on February 27th at Beirut, Syria. He was born at Ottawa, Canada, educated in arts at Toronto University, and graduated B.A. at 20 years of age. He took his medical degree at Michigan University, and directly afterwards was commissioned by the American Board a missionary to Turkey and served four years in the Aintab Medical College until the Turks closed the school. Thence he was called to Beirut, where he served so brilliantly for a generation, coming to the American University of Beirut in 1889. In 1892 he had leave to study in Koch's laboratory, and at other times he worked in Berlin and Vienna. He advanced evidence that *Culex* is the carrier of the dengue germ, and was the first to isolate that microbe. He had an extensive practice, and spoke all the principal languages of the Levant. He was a teacher of great force and inspiration, a remarkable diagnostician, and a most skillful therapist. Many an officer who was sick in the American penitentiary came under his care, and all such will mourn his passing away. He was the chairman of the Beirut Executive Committee of the Lebanon Hospital for the Insane, an Anglo-American charity in the suburbs of Beirut, the only institution of the sort in Syria.

Medical News:

THE conference of representatives of voluntary hospitals in England and Wales to discuss the report of the Council of the British Medical Association on hospital policy was held at the Wigmore Hall, London, W., on March 22nd, under the chairmanship of Sir James Galloway. The Association's recommendations were generally approved by the meeting. A full report of the proceedings will appear in our next issue.

SIR THOMAS OLIVER will give an address on alcohol in relation to industrial hygiene and efficiency before the Society of Arts, John Street, Adelphi, W.C., on Wednesday, March 29th. Sir Robert Armstrong-Jones will take the chair at 8 p.m.

At a meeting of the Illuminating Engineering Society to be held at the house of the Royal Society of Arts (John Street, Adelphi, London), at 8 p.m. on Tuesday, March 28th, there will be a joint discussion with the Royal Institute of British Architects on the lighting of public buildings: scientific methods and architectural requirements. An account of experimental work and results will be given by workers at the National Physical Laboratory.

The Central Association for the Care of the Mentally Defective has changed its name to the "Central Association for Mental Welfare." Its offices are at 24, Buckingham Palace Road, S.W.

THE President of the French Republic has awarded the gold "Médaille de la Reconnaissance Française" to Miss Ruth Nicholson, M.B., B.S.; for her distinguished services to the French soldiers at Rongemont and Villers Cotterets.

UNDER the auspices of the National Institute of Industrial Psychology a meeting will be held at the Mansion House on Monday, March 27th, at 4.30 p.m., to consider the importance, in the present industrial and commercial situation, of eliminating wasteful and misapplied effort by a more systematic application of human energy. Mr. H. J. Welch will be in the chair, and among the speakers will be Lord Haldane, Mr. W. L. Hichens, and Dr. C. S. Myers.

The annual meeting of subscribers of the Cremation Society of England will be held at 52, New Cavendish Street, on Wednesday, March 29th, at 3 o'clock.

THE name of Dr. R. W. Starkie, who, on September 16th, 1921, was sentenced, at the Central Criminal Court, to nine months' imprisonment for administering drugs with intent to procure abortion, has been removed by the Minister of Health from the medical list of the London Insurance Committee as from March 15th, 1922. Dr. Starkie appealed against his conviction, and the Court of Criminal Appeal recently gave a considered judgement, dismissing the appeal.

At a meeting of the Association of Economic Biologists, to be held at the Imperial College of Science, South Kensington, at 2.30, on Friday, March 31st, Dr. W. Lawrence Balls will read a paper on the advantages and defects of team work in economic biology. Dr. Franklin Kidd will also read a paper on fruit storage.

THE King of Italy has conferred the Italian silver medal "Al Merito della Sanità Pubblica" upon Major Myer Coplans, D.S.O., O.B.E., in recognition of services rendered during the late war.

THE Chadwick Public Lectures are this year being given between March and June. Already lectures have been given in London by Professor Van Loghen and Mr. H. E. Stigöe, and another lecture will be given by the latter in the gallery of the Royal Institute of British Architects, 9, Conduit Street, W., on Thursday, March 30th, at 8 p.m., on "Water, its distribution and use." Sir Arthur Newsholme is giving a course of three lectures, on "Relative values in public health work," in the large lecture hall of Birmingham University, on March 27th, 28th, and 29th, at 7.30 p.m. On May 4th and 11th, at 5.15 p.m., Sir Lawrence Weaver will lecture on "Rural resettlement and its relation to public health," at the Royal Society of Arts, John Street, Adelphi. Mr. E. Augustus Bowles will lecture on "Superstitions of early herbalists," at the Chelsea Physic Garden, on May 25th; and Professor S. D. Adshad will lecture on "Housing and town planning," in Belfast, on a date not yet fixed. Full particulars of the Chadwick Lectures may be obtained from the Secretary of the Trust, 13, Great George Street, S.W. 1.

The Department of Scientific and Industrial Research has published a second edition of the English translation of Gleichen's *Theory of Modern Optical Instruments*. The price of the book, which is issued by H. M. Stationery Office, is 12s. 6d., and it can be obtained through any bookseller. The appendix on range finders has been omitted from this edition, as a book on the subject is about to be issued by a firm of publishers.

WE have received the first number of the *Safety News and Chronicle*, a new bi-monthly publication dealing more particularly with the use of respiratory appliances for work in poisonous or irrespirable air, diving, etc., but also with safety devices generally. The number contains excellent popular articles by Professor Leonard Hill on workshop hygiene, and by Wing Commander Martin Flack on safety in the air. An account by Mr. Walter Clifford, Superintendent of the North Staffordshire Mine Rescue Station, gives a vivid impression of the sort of work which has been done after great colliery explosions by mine rescue teams. Another article describes the organization and work of the London Fire Brigade's "Poison Gas" teams; and the concluding article contains a fascinating account of the early development of diving bells. There are numerous illustrations, one of which is a photograph of a mule loaded with the oxygen cylinders which are being taken out with the Mount Everest Expedition. To judge from this first number, medical readers will find much to interest them in this new publication.

Mr. JUSTICE McCARDIE gave judgement in the King's Bench Division on March 9th, in an action for damages for alleged negligence against Dr. E. C. Montgomery-Smith in the treatment of a fracture of the tibia and fibula in a married woman. His Lordship, according to the report in the *Times*, said that the case turned to a very large extent on the credibility of lay evidence. He could accept neither the evidence of the husband nor of the wife. He was satisfied that Dr. Montgomery-Smith had suggested the use of the x rays, whereas the case against the defendant was that according to the plaintiff he expressed a definite opinion against the use of x rays. He could find no reason why the defendant should not suggest an x-ray examination, as he realized that there was a serious fracture. He was satisfied that the defendant diagnosed the case with adequate care, that the foot was properly set, and that everything was done to put it right. He found that the injury was not due to the defendant's negligence, but to what the plaintiff did since the injury. The onus was upon the plaintiff to prove negligence and she had failed. There was, therefore, judgement for the defendant with costs. The defendant's case was conducted for the London and Counties Medical Protection Society.

STRATHPEPPER has joined the British Spa Federation, which now comprises Bath, Buxton, Cheltenham, Droitwich, Harrogate, Llandrindod Wells, Leamington, Woodhall, Strathpeffer, and New Zealand.

DURING December last 1,800 fatal cases of plague occurred in Java.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the **BRITISH MEDICAL JOURNAL** are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR OF THE BRITISH MEDICAL JOURNAL, *Aitology, Westrand, London*; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate, Westrand, London*; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Mediseera, Westrand, London*; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 15, South Frederick Street, Dublin (telegrams: British Medical Association 737, Dublin) and of the Scottish Office: 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

QUERIES AND ANSWERS.

CATHETER LUBRICANTS.

DR. G. M. WILCOCKSON (Guildford) writes in reply to "X. Y. Z." (p. 461): I have a patient, aged 81, who has had to use a catheter himself for the past ten years. About six years ago it began to give him much pain. I prescribed the following ointment, which he has used ever since with great relief:

R. Atropine sulph.	}	āā gr. ij
Cocaine hydrochlor.		
Vaseline		ad ŷ ss

The catheters should be kept thoroughly sterilized.

NOTE.—It is against the rules of the Post Office to receive *post* instant letters addressed either in initials or numbers.

MEDICINE.

274. Recent Work on Digitalis Treatment.

LDENS (*Klinische Wochenschrift*, February 18th, 1922) gives a critical review of recent work on the action of digitalis preparations, which is unsuitable for brief abstract, but the following points of practical importance may be noted. Owing to the difficulty in comparing the value of various preparations in clinical work, pure active principles have been separated and employed—strophanthin and digitoxin. Only strophanthin is suitable for intravenous use: digitoxin has not proved reliable in practice. The relative values of various preparations have been estimated by their action on the frog's heart, but the results are not always reliable for clinical work. Digitalis leaf contains digitoxin, digitaline, and gitalin. Cymarine, having an action similar to digitalis, can be separated from the root of *Japocynnum cannabinum*. Since all forms of digitalis are of service in suitable cases, it is not easy to determine which is the most powerful clinically, for many reasons. Krehl and others speak highly of verodigen. For intravenous treatment the author prefers strophanthin. *Scilla maritima* has recently been strongly recommended by Mendel, especially for aortic insufficiency, and also in cardiac failure in myocarditis, emphysema, and kidney diseases. The author considers cymarine has no advantage over digitalis and strophanthin. Respecting Fraenkel's intravenous strophanthin treatment, no new work has been published, but the author urges caution in its use. Deaths have occurred from an overdose. Wolfer recommends digitalin intravenously, since no fatal results have followed. If digitalis fails when given by mouth, good results may be obtained by rectal administration. In cases of hepatic congestion, when, through disturbance of the portal circulation, the absorption from the gastro-intestinal tract is hindered, the rectal administration of digitalis deserves more consideration than it has hitherto received.

275. A New Technique for Intramuscular Injections of Calomel.

PONTOPPIDAN (*Ugeskrift for Læger*, January 12th, 1922) points out that though the intramuscular injection of calomel has proved to be remarkably effective, its general use is discouraged by the risk of severe poisoning and considerable pain at the site of injection. The poisoning, he thinks, may be largely due to the unwitting administration of too big doses; in a suspension the calomel is apt to settle in the bottle, so that the more there is taken from it the higher grows the concentration of what is left, and in the end the patient may be given 20 to 30 eg. of calomel when the physician imagines he is giving only 5 eg. To obviate this serious objection the author suspends his calomel in cocoa butter, each 15 eg. pill or short rod of which contains 5 eg. of calomel. At room temperature these rods are as hard as snet. Made to fit exactly into an ordinary 1 c.cm. Record syringe, they are gently warmed in this syringe till they melt, and they can then easily be injected. To empty the needle completely the syringe is detached from the needle while this is still in the body, a little air is aspirated into the syringe, and is then injected through the needle, forcing all that is left in the needle into the tissues. The author adds two technical details: the injection should not be started till all the cocoa butter is melted, and the apparatus should be cleaned with spirit or ether directly after an injection. Without these precautions the needle is apt to get blocked, and it then requires renewed heating.

276. Pulmonary Diseases Confused with Tuberculosis.

OTIS (*Boston Med. and Surg. Journ.*, January 12th, 1922), from the fact that from 40 to 60 per cent. of the men invalided from the army as suffering from tuberculosis were subsequently found not to have the disease, points out that a mistaken diagnosis is not at all uncommon. Among frequent errors in diagnosis are chronic affections of the upper respiratory tract—for example, nasal obstruction, chronic nasopharyngitis, and disease of the sinuses and tonsils—which cause chronic cough, mucopurulent expectoration, and symptoms of bronchitis or tracheo-bronchitis. For this reason the upper respiratory tract should always be examined to eliminate the possibility of error. Since post-influenza conditions may closely simulate an active tuberculosis diagnostic error can only be avoided by frequent examinations of the sputum, and by keeping the patient under close

observation; and the same applies to some cases of acute bronchitis and bronchiectasis. The assumption that all pleurisies are tuberculous in origin is unwarranted, since some recover completely without giving rise to any further tuberculous manifestations. In pneumoconiosis it is not justifiable to diagnose tuberculosis because the patient has been exposed to inhalations of irritating dust, tuberculosis in these cases being an end-result through the lungs having been wounded by long exposure to such irritation. There is no evidence to show that gas inhalation in "gassed" soldiers conduces to tuberculosis, though many are suffering from chronic bronchitis and bronchiectasis.

277. Diabetic Oedema and Acidosis.

FÖLDES (*Wien. Arch. f. inn. Med.*, Band III, Heft 3) mentions the various views which have been held as to the cause of the oedema which sometimes occurs in severe cases of diabetes mellitus. He records a number of observations, which he considers are indications that oedema only occurs when acidosis is present (positive Gerhardt's ferric chloride reaction in the urine). His conclusion is—without acidosis, no oedema. The tendency to oedema may remain long latent until one of the following factors comes into play: (1) Sudden increase of acidosis as produced by the rapid withdrawal of carbohydrate food; (2) decrease of the polyuria, associated with diminution of the glycosuria, as occurs during fasting or when the diet is restricted to vegetables; (3) salt and water detention through treatment of the acidosis with sodium bicarbonate. Often all three factors are combined. The oedema frequently disappears if the acidosis ceases, or if the diuresis increases, or if the administration of sodium bicarbonate is discontinued. The author shows that hydraemia constantly accompanies the oedema of diabetes, and after a long consideration of the pathogenesis he concludes that acidosis leads to a predisposition to oedema or to manifest oedema, through an affection of the kidney functions, in consequence of which the excretory power of the kidneys for salt and water is diminished.

278. Prophylaxis of Measles.

THE injection of serum obtained from donors was tried during a recent epidemic of measles of moderate severity in Rochester, Minn., U.S.A., and the results are reported by MCNEAL (*Journ. Amer. Med. Assoc.*, February 4th, 1922). The donors were free from tuberculosis and syphilis, and had passed through fairly severe attacks of measles, without complications or sequelae. They were bled after an interval of five, seven, or nine days from the disappearance of the fever. The serum was bottled in amounts of 5 c.cm., preserved with 0.01 per cent. tricresol, and kept in the ice-box until used. After varying periods following exposure, sixteen recipients were given 5 c.cm. of the serum, injected into the muscles of the thigh. None of the children had ever had measles, although they had come in intimate contact with patients during the contagious period. Four of the sixteen developed an extremely mild type of measles, but no complications or sequelae. In three of the four patients the incubation period was lengthened to nineteen days. Twelve children remained free from measles. One child contracted measles two months after successful inoculation; this suggests that the immunity does not persist longer than sixty days in some cases. The method, according to the author, recommends itself highly for the prevention of measles during the period of danger, between the ages of 5 months and 6 years, in tuberculous children and in those physically below normal. In institutions in which large numbers of frail children are intimately associated the procedure might be of great value.

279. Intravenous Treatment of Pruriginous Skin Diseases.

STRASSBERG (*Wien. Min. Woch.*, December 8th, 1921) has recently employed intravenous injections of a 50 per cent. solution of glucose in obstinate cases of pruriginous dermatoses; 10 c.cm. daily were given at first, but later 2 c.cm. of the solution were used, as better results were obtained with smaller doses. In a particularly obstinate case of urticaria in which all other methods were unsuccessful an intravenous injection of glucose was able not only to stop the irritation at once but also to prevent any further eruption. In other cases of urticaria and prurigo senilis the effect of the glucose was not so striking, but as a general rule the irritation could be diminished even in very severe cases of urticaria, while pruritus without visible skin changes was only slightly affected.

EPITOME OF CURRENT MEDICAL LITERATURE.

MARCH 25, 1922]

nodular and omental metastases were successfully removed in a patient, aged 28. The importance of treating the bladder and ureters when necessary is shown by the finding of Simmonds that over 50 per cent. of patients with cervical cancer die of pyelonephritis and uremia; the writer has had one case of cure after resection and implantation of the ureter and one after excision of the vesical trigone. The mortality of the operation is given as 15 to 20 per cent.; but this rate should be considerably reduced by the following means: (1) Careful preoperative local treatment, consisting of irrigation and application of hydrogen peroxide and ure of iodine in succession; (2) the use of local and general anaesthesia in debilitated subjects; (3) changes of the operative field during the operation with lavage of the operative field with hydrogen peroxide; (4) increased employment of the suprapubic or abdomino-vaginal operation, which is of shorter duration and is attended with less shock than the abdominal method; (5) combination of operative with radium therapy. In the writer's hands the mortality was 10.3 per cent. among 93 cases and 6.4 per cent. in his last 74.

291. Duration of Life in Cancer of the Uterus.
STIGEL (Zentralbl. f. Chir., January 7th, 1922) has made a study of the length of survival in cases of cancer of the uterus observed at the Glessen Gynaecological Clinic during the period 1905-13. He comes to the whole to similar conclusions to those of Krönig; but while Krönig reckons the average length of survival of inoperable cases, and of operated cases at one and a half years, Siegel found that the average length of survival of inoperable cases was two and a quarter years, and of operated cases two and three-quarter years, so that operation prolonged life for six months on the average. Five years after the commencement of treatment with only 13 per cent. of the inoperable. In cases of carcinoma of the body of the uterus the outlook is somewhat better. Siegel therefore regards irradiation of operable tumours as justifiable, and recommends that radical operations with a high mortality should be superseded by slighter operations followed by intensive x-ray treatment.

PATHOLOGY.

295. The Goldsol Test in Mental Disease.
BENFORD (Journ. Mental Science, January, 1922) regards the goldsol test, from its greater reliability and simplicity of technique, as preferable to the Wassermann reaction in the diagnosis of neuro-syphilis, since it merely consists in making ten saline dilutions of the spinal fluid, adding the goldsol reagent, and interpreting the results by the degree of precipitation. Typical well-marked reactions are obtained only in general paralysis, tabo-paresis, and juvenile paresis, the percentage therein of positive reactions being 95. Comparisons made in 250 cases showed the reaction to be as reliable as the Wassermann, and it is helpful in the detection of early disease; and may prove of more value in the diagnosis of congenital syphilis than any other test. Its simplicity as compared with the Wassermann test, and the facts that it only occupies a few minutes and that only a few drops of the spinal fluid are required, are important points in its favour. It is not applicable to blood serum as a means of diagnosing general paralysis, because a dilution corresponding to 0.08 per cent. causes precipitation of gold in the same way as a strongly positive parietic fluid, but the presence of a small amount of blood in the spinal fluid does not render it unfit for testing. The chief drawback is the uncertainty of being able to prepare a good goldsol at every attempt.

296. Streptococcal Infections of the Heart.
COOMBS (Quart. Journ. of Med., January, 1922) describes the two main types of streptococcal infection of the heart—namely, the simple rheumatic carditis and progressive ulceration of the endocardium. Of these the former occurs chiefly in childhood or adolescence and is really a pancarditis, all parts of the heart—myocardium, endocardium, and pericardium—being attacked simultaneously. There are many intramyocardial foci of inflammation characterized by intracellular degeneration and interstitial proliferation, the focal reaction running a brief course and recurring from time to time. The electrical changes which result from the healing of these foci lead to degeneration of the myocardium, and the patient dies as the result of the mechanical embarrasments which the electrical changes impose on the action of the

heart. It is believed that this variety of carditis is the result of the invasion of the heart by streptococci through the coronary blood supply, the process being frequently repeated. In ulcerative endocarditis, the second type of streptococcal infection, the organisms attack the endocardium only, and such lesions of the heart muscle as may occur are secondary to the endocardial lesions and probably embolic in origin. In ulcerative endocarditis the streptococci may either invade the valves from the surface or be carried to them by the coronary vessels, and the original source of infection can often be traced to some streptococcal focus of inflammation, such as puerperal sepsis. The infective agent may even be derived from the common streptococci which follow the respiratory tract. The cardiac lesions which follow when animals are inoculated with streptococci intravenously belong to the type of ulcerative endocarditis; there is widespread endocardial inflammation and necrosis, with myocardial lesions of vascular origin. The main conclusions of the author are that both rheumatic carditis and ulcerative endocarditis are lesions of the heart due to streptococci; in the former infection is due to small doses of streptococci carried to the heart muscle by the coronary artery and frequently repeated, whereas the latter bears a strong resemblance to the effects produced by the intravenous injection of a large dose of streptococci.

297.

The Red Blood Cells in Cancer.
ROBIN (Les Néoplasmes, No. 1, January, 1922), after a review of the literature on the condition of the red cells in cancer and a statement of his own results, expresses the following opinions. Low red cell counts are commonly found in cancer, but there is no relationship between the anaemia and the gravity of the symptoms. The red cell counts are markedly variable in the same patient from time to time, and may even oscillate to a point above the normal. In the majority of cancers the colour index is reduced to 3/4 or 1/2, but the loss in haemoglobin is occasionally not so great as the reduction in red cells, with the result that a colour index of above 1 is obtained. Such a case might be easily mistaken for pernicious anaemia. Irregularities of staining, polychromatophilia, and basophilia are commonly found in the red cells of cancer blood, and, since they are more frequently found in advanced cases, these signs should be regarded as of evil omen. Irregularities of size and shape of the red cells are almost the rule in cancerous anaemia. Nucleated red cells are found in 30 per cent. of cancer cases, but they are seldom numerous, and require to be searched for carefully. They are, of course, common to all secondary anaemias, and their presence is of no value either for diagnosis or prognosis. Robin finds that the red blood cells in cancer are more resistant and less easily haemolysed than red cells of normal blood, and he looks on this as a mechanism of defence against the multiple causes of destruction to which they are exposed.

298. Surface Tension and the Bactericidal Power of Certain Disinfectants.

CHRISTIANSEN'S demonstration that the disinfecting power of the alcohols bears a relationship to their superficial tension, HANSEN (C. R. Soc. Biologie, January 28th, 1922) has brought forward evidence which suggests that other factors are involved besides those of purely physical nature. Working with a culture of *Staphylococcus aureus* he investigated the disinfecting power of alcohol and hydrochloric acid, at first separately and then combined. As a result he finds that their joint action is very much stronger than would be anticipated from a consideration of either of them singly. That this effect is not merely one of surface tension is shown by the fact that it is not brought about by other substances, such as saponin or peptone, which exert a marked lowering of surface tension, while, on the other hand, it is obtained by such substances as methyl or propyl alcohol and even by acetone. The probable explanation is that the alcohols act by increasing the permeability of the bacterial membrane to the disinfecting substance, the adsorption of which is regulated by the surface tension.

299. Tubercle Bacilli in the Blood.
ALBERTARIO (Tuberculosis, December, 1921) has examined the blood of 100 cases of tuberculous (mostly pulmonary) with a view to the detection of tubercle bacilli. He took 4 to 5 c.cm. of blood, let it coagulate, removed the serum without touching the upper part of the clot (preferably with sulphuric acid, fixed zone), spread on a slide washed with Ziehl. Of the 100 cases with alcohol and stained with Ziehl. Of the 100 cases examined, 52 gave a positive result, mostly where the temperature was raised, and in some scattered tuberculous lesions without pulmonary affection. In 8 early cases tubercle bacilli were found in the blood, although repeated examination of the sputum gave a negative result.

Two "Armour" Preparations of distinct value in Gynaecology.

Corpus Luteum "Armour" can always be relied upon.

The particular conditions for which Corpus Luteum "Armour" will be found serviceable, are:—

1. Functional amenorrhœa or scanty menstruation;
2. Dysmenorrhœa of ovarian origin;
3. Neurasthenic symptoms during menstrual life;
4. Sterility not due to pyogenic infections or mechanical obstruction;
5. Where the function of one ovary is impaired, or one ovary has been removed, and the compensatory activity of the other is insufficient; and
6. Hyperemesis in the early months of pregnancy.

Corpus Luteum "Armour" is supplied in 5-gr. Tablets and Capsule Form (2 and 5-gr.)

Ovarian Substance "Armour."

Is especially concerned in menstruation, uterus action, and nutrition generally (especially the poor nutrition during pregnancy). It is a great aid in osteomalacia and other disorders attendant on double ovariectomy. In climacteric disorders and the far-reaching effects at the sudden menopause, and the numerous disorders following in its wake—ovarian therapy is invaluable.

OVARIAN SUBSTANCE has a marked effect in restoring the inorganic salts lost through cœphalism and menstrual disorders. Where asthenia, amenorrhœa, and chlorosis are due to lowering of the ovarian secretion—ovarian substance therapy has a distinct place.

Ovarian Substance "Armour" is supplied in 5-gr. tablets. Each tablet representing 14-grs. of fresh ovary of the cow.

To ensure obtaining our preparations specify "ARMOUR."

THE LOTUS FLOWER was the principal plant form adapted to artistic purposes by very early Egyptian pioneer decorators and consequently the source of a "great part of the world's ornament." In estimating mankind's debt to ancient Egypt our minds are constantly brought back to "the flower which was in the beginning the glorious Lily of the great water," for from it the Egyptian as "father of the world's ornament" drew his chief inspiration. The Egyptians were extraordinarily fond of flowers, and very early perceived the beauty of plant form, especially that of the lotus, which they adapted to serve the purposes of architectural art, and which they painted—open flower, bud, calyx, leaf and seed-vessel—upon everything they wished to decorate. The art thus called to life by the lotus has survived to the present day; it descended to classic times and is exemplified in the anthemion of the Greeks; it appears as an important element in Indian and Mohammedan ornamentation; all Europe inherited it through Greece; the fleur-de-lis is a conventional development of it.

The oldest application of the lotus to ornamentation was two flowers tied together by their stalks, as in the illustration on the left. It is already found on "prehistoric" pottery, and is seen to great advantage in the IVth dynasty.

BYNO

Hypophosphites

An ideal tonic in general debility
and in convalescence following
acute disease.

'Byno' Hypophosphites has shown itself to be an excellent tonic for invigorating the system after severe illness. It is of proved value also in general debility, acting as a mild but efficient restorative. The 'Bynin' Liquid Malt renders the preparation easy of absorption and in this respect it is a distinct advance on the official syrup of hypophosphites, which in many cases of impaired digestion is not well tolerated. In convalescence following Typhoid and also Influenza it reduces anæmia and improves the general tone. Where nervous exhaustion is associated with impaired gastric functions it is at once a stimulant and digestive.

THE NATURE AND SIGNIFICANCE OF HEART SYMPTOMS.

BY

SIR JAMES MACKENZIE, M.D., F.R.C.P., F.R.S.

(From the Institute for Clinical Research, St. Andrews.)

I. STIMULI CONCERNED IN THE HEART BEAT.

INTRODUCTION.

IN 1905 I published in this JOURNAL a series of articles on "New methods of studying affections of the heart." The articles were the outcome of a research in which I had been engaged for nearly twenty years. A basis was laid for the differentiation of abnormal rhythms, and the practical importance of the research was illustrated by the action of digitalis. The varied and seemingly capricious effect of digitalis on the human heart was demonstrated to be due to the fact that digitalis may act in one way on a diseased heart and another on a normal heart, and that the drug may act differently in different diseases. Although the methods have been greatly improved, especially since the introduction of the ink polygraph and the electro-cardiograph, and a great deal of light has been thrown upon the mechanism of abnormal rhythms, little real advance has been made in the understanding of matters essential for the intelligent practice of medicine, such as the significance of symptoms and the effects of remedies. It has long been evident that a new concept was needed if these essentials were to be acquired. At the Institute for Clinical Research at St. Andrews we have given particular attention to this aspect of the subject, and we have been able to recognize some of the fundamental principles concerned in the production of the symptoms of disease. The application of these principles to the interpretation of cardiac phenomena has shed fresh light upon the subject which enables us to present the symptoms of cardiac affections in a way that brings out their peculiar significance and opens up new fields for exploration.

The Development of the Heart.

At an early stage of development the heart is represented by a tube, which is pulsatile, the contraction starting at a definite part which in later development becomes the sinus venosus. In the course of development pouches are formed on the side of the tube which ultimately become the auricle and ventricle. Sir Arthur Keith has drawn for me a diagram (Fig. 1) which represents a stage of development. Here the

FIG. 1.—Diagram representing an early stage in the development of the heart. P.C.T. is the primitive cardiac tube, on the sides of which there develop pouches A and V, which become the auricles and ventricles. The primitive cardiac tube in the fully developed heart is probably represented by the conducting system, shown in Fig. 2.

have been evolved were originally identical, but as development proceeded the cells became modified to meet the functions imposed upon them. At first each cell could not only contract but could produce the stimulus which caused contraction. Thus it is that while originally the cells of the primitive cardiac tube were contractile as well as stimulus-producing, they gradually lost their power of contraction, but developed the function of stimulus production and conduction, to meet the requirements of the new arrangements for contraction.

The cells of the auricle and ventricle, on the other hand, not in any special degree develop the stimulus-production

or conductivity function, which remained primitive, but developed the contractile function. Though it is true that all cells of the heart have the power of stimulus production and of conductivity, they have them in a very unequal degree.

In the course of development some peculiar influence is acquired whereby the older tissues represented by the conducting system control the muscle cells of the auricle and ventricle, and it is the loss of this control that enables the muscle cells to show their peculiar nature, as in auricular fibrillation and the idio-ventricular rhythm.

The Constitution of the Heart.

From this way of looking at the matter we can recognize two main structures in the heart concerned in its action, differing widely in structure and in function:

(1) A conducting system, consisting of peculiar cells of two kinds:

- (a) The pale filiform cells constituting the sino-auricular and auriculo-ventricular nodes.
- (b) The large cells, known as the Purkinje cells, which constitute the auriculo-ventricular bundle, and are also found in the walls of the auricles and ventricles:

(2) A contracting system, consisting of the peculiar muscle cells of the auricular and ventricular walls.

There are also nerve cells and fibres, from the vagus and sympathetic nerves, which take part in regulating the sino-auricular node. The valve apparatus is, for the present, not considered.

The Manner of the Starting of the Heart's Contraction.

Before dealing with the features of the different rhythms of the heart it may be as well to indicate the view accepted as to the rôle each part plays in a cardiac revolution.

It is recognized that all the tissues of the conducting and contracting systems just mentioned have the power of starting a contraction. It is recognized that in the normally acting heart the contraction first starts in a collection of peculiar cells situated at the mouth of the superior vena cava—the sino-auricular node (S.A.N., Fig. 2).

It is assumed that these cells have the power of obtaining material from the blood which, when a sufficient quantity has been stored, renders this node so susceptible to stimulation that it readily discharges a stimulus which causes the auricle to contract. The stimulus passes through the auricle to the auriculo-ventricular node (A.V.N., Fig. 2). Here the same process has been going on as that described in the sino-auricular node, and in response to the impulse from the sino-auricular node the auriculo-ventricular node discharges its stimulus. From the auriculo-ventricular node the impulse is conveyed by the auriculo-ventricular bundle (A.V.B., Fig. 2) to the ventricle, which responds by a contraction.

Such in brief is the view which the present state of knowledge enables us to give of the normal rhythm of the heart. It will be seen that the functions of the conducting system are (1) to originate a stimulus which excites the auricle and ventricle to contract—hence we speak of this function as stimulus production; and (2) to convey the stimulus by a special path—hence we speak of the function of conduction.

There are many abnormal rhythms, due to the fact that the cells, both of the conducting system and the contracting system, possess under certain circumstances the power of starting a contraction. The reason that these cells do not start independently in the normal state is that the sino-auricular node reaches the susceptible stage and "goes off"

FIG. 2.—Diagram representing the two main systems concerned in the heart's action.

node (A.V.N.) and bundle (A.V.B.). In both auricles and ventricles are also Purkinje fibres which belong to this system, represented by the scattered cells (P) in the auricle. The vagus (Vag.) is also shown.

earlier than the other parts of the conducting system, so that before they are ready to start off by a local stimulus they receive the stimulus from the sino-auricular node. The starting places in the conducting system lower than the sino-auricular node become stimuable later than the sino-auricular node; the auriculo-ventricular bundle, for instance, if it does not receive the stimulus from above goes off about thirty times a minute.

Under abnormal circumstances the heart beat may start from a stimulus arising in any part of the conducting system and also in the muscle cells of the auricle and ventricle. There is a marked difference in the heart beat which arises in any part of the conducting system from that which arises in the muscle cells of the contracting system (auricle and ventricle).

The Character of the Heart Beat Originating in the Conducting System.

The normal heart beat, starting at the sino-auricular node, sends a stimulus which affects in orderly sequence the parts below. It is well regulated and proceeds at a pace which leaves time for the cells in all parts to perform their function in a manner likely to be efficient—that is, with sufficient time for them to rest, and to accumulate a sufficient store of nutritive material for the efficient performance of their functions.

The normal beat takes place when all tissues have time to be completely restored. Moreover, the beats which originate lower down in the conducting system, in the auricle (in tissue which I hypothesize is present, as distinct from the ordinary auricular muscle fibres), in the auriculo-ventricular node and bundle, all result in a well-ordered, powerful contraction of the ventricle.

The Electro-cardiogram.

When a muscle contracts it generates a current which can be led from the body and made to activate a string galvanometer. The movements of the string or thread that result can be photographed. In such a photograph certain characteristic movements are recorded, due to the contraction of the auricles and ventricles, which permit some useful deductions to be made as to the place where the heart's contractions start.

The electro-cardiogram of the normal heart beat is distinctive. It is shown

in the last part of Fig. 3, where each cardiac revolution is represented by the waves P, R, T; P is due to the auricular systole, while R and T are due to the ventricular systole.

In this record the beats marked P, R, T are normal beats.

When the starting place of the heart's contraction is at some other place than the sino-auricular node the position and character of the P wave are altered. In the rhythm arising in the auricle the P wave is inverted. I suggest that in such an instance the contraction arises in some part of the conducting system in the auricles. Hitherto there has not been discovered a direct connexion between the sino-auricular node and the auriculo-ventricular node; but G. A. Gibson² pointed out thirteen years ago that Purkinje cells were to be found in the auricle, an observation confirmed lately by Holmes.³

Such cells must be there for a purpose, and that purpose is likely to be the same as in other parts of the heart. There is a great difference between heart beats which presumably start in these cells and the beats which start in the muscle cells (as in auricular flutter and fibrillation), as we shall see later. Moreover, such an electro-cardiogram as Fig. 4 shows an inverted P wave at the beginning, which gradually changes

its character till it becomes upright and normal, suggesting that the stimulus arose at first outside the sino-auricular node, but gradually crept back along a path to the sino-auricular node.

Characteristic electro-cardiograms arise in the auriculo-ventricular node and bundle. All electro-cardiograph records of the ventricular contraction when the stimulus enters the ventricle by the bundle show the R, T waves. When the stimulus for contraction arises in the ventricle the electro-cardiogram is different, representing usually the features shown by the extra-systole (*ex.-sys.*) in Fig. 3.

The Idio-ventricular Rhythm.

The term "idio-ventricular rhythm" is used here to describe the contractions that arise in the muscle cells of the ventricle. It has been used variously, as for the ventricular contraction in complete heart-block, but there the contraction does not arise in the cells of the ventricle but in the cells of the remains of the bundle, and the electro-cardiogram shows the usual ventricular R, T waves, indicating that the stimulus

entered the ventricle by way of the bundle. There are several kinds of ventricular rhythms, but one form only is dealt with here.

The occasional irregularity which goes under the term of ventricular extra-systole is

due to a contraction which arises in the ventricle, and is quite independent of the stimulus coming down the bundle from the auricle, as shown in Fig. 3, where the large movement (*ex.-sys.*) is due to a ventricular extra-systole. In place of a solitary contraction, which is usual, a number of these ventricular systoles may occur and produce a persistent abnormal rhythm (the idio-ventricular rhythm). This rhythm, however, is rarely entirely composed of these beats, but is interrupted by a pause, followed by a beat arising in the normal way. The abnormal rhythm is therefore characterized by groups of small beats interrupted at varying intervals by one or two large normal beats, as shown in Fig. 5, where there are two groups of these idio-ventricular beats. The diagram (Fig. 6) explains the tracing, and shows that the auricle is pursuing one rhythm, and that for the most part the ventricle is pursuing another and more rapid rhythm, interrupted by a beat which comes down from the auricle in a normal manner, shown in the diagram by a line passing across the space of the A.C. interval. The electro-cardiogram of the idio-ventricular beat shows a series of large waves like those of the extra-systole in Fig. 3.

The Output of the Ventricles.

While the electro-cardiograms show characters distinctive of the places from which the rhythm starts, there is other evidence which throws an unexpected light on the heart beat, the most important being the effect of the abnormal rhythm on the output of the ventricles. The consideration of this part of the subject gave rise to an inquiry into the cause of ineffective beats, which has led to a new field of investigation, and for this purpose we have to go back to the study of the sphygmogram of the radial pulse. We recognize that sphygmographic records give a somewhat imperfect conception of the output, but, imperfect as they are, they are the best we have and are of real value.

But these pulse records are of value also in that they throw light on processes going on within the heart whose recognition is essential to the understanding of the mechanism—such, for instance, as the part played by the conducting system and by the muscle cells of the left ventricle during abnormal rhythms. We will therefore consider the subject here from this point of view.

FIG. 3.—The electro-cardiogram of ventricular extra-systoles. In the first part of the record are three normal beats, P, R, T, followed each by an extra-systole (*ex.-sys.*). The beats (P, R, T) at the end are normal. The type of radial pulse which the extra-systoles produced is seen in the latter part of Fig. 11, where the extra-systolic beats failed to reach the radial artery.

FIG. 4.—Electro-cardiogram of a rhythm starting in the conducting tissue of the auricle, and passing to the sino-auricular node. This is shown by the inversion of the P wave at the beginning of the record, and the gradual change of the wave in the upright at the end of the tracing, where the record is normal. (Cohn.)

(a) *The Output of the Ventricle in Beats arising in any Part of the Conducting System.*

We expect that under normal circumstances the contraction of the muscle cells of the ventricle will be so organized that they will contract in such a manner as to facilitate the expulsion of the contents. This organized mechanism is dependent on the manner in which the stimulus enters the ventricle and on the nature of the stimulus. In the various electro-cardiograms the stimulus which arises above the ventricle, whether in the sino-auricular node, the auricle, the auriculo-ventricular node, or the auriculo-ventricular

bundle, all produce the same type of ventricular electro-cardiogram. Moreover, in all the rhythms arising in the conducting system there is also an effective contraction of the ventricle. The size and force of the beat depend, within certain limits, on the rate, inasmuch as more blood will have accumulated in the ventricle, and consequently more will be expelled when the rate is infrequent than when it is frequent. The infrequent radial pulse in complete heart-block is strong and forcible.

(b) *The Output of the Ventricle in Beats due to Extra-systole.*

In extra-systoles of the auricle the impulse travels from the auricle by the bundle and enters the ventricle by the usual path, producing usually an effective output. Hence an extra-systole of the auricle may be of good size—smaller than the normal beat merely because it is premature, and in consequence the ventricle is not as full when it contracts in response to the premature auricular stimulus as it does to the normal.

Extra-systoles in the ventricle arise in some part of the muscle cells, and the wave of contraction therefore does not sweep through the walls of the chamber in the normal manner. This is seen in the character of the electro-cardiogram, as in Fig. 3. As the contraction spreads to the muscle cells in a way different from the normal the output is greatly diminished; this is well seen in the small beat which usually results from a ventricular extra-systole, or in the absence of a beat in the radial pulse, as in Fig. 11.

(c) *The Output of the Ventricle with the Idio-ventricular Rhythm.*

As the idio-ventricular beats are of the same nature as ventricular extra-systolic beats, the output of the ventricle is greatly lessened, and the radial beats are in consequence very small. This is brought out in Fig. 5, where there are a series of small beats, due to beats arising from a stimulus in the ventricle, interrupted by large beats arising in the normal way. In the tracing from the jugular pulse it will be seen that the beats of the auricle (a) are regular, and undisturbed by the numerous small ventricular beats. These latter occur in groups, and at the end of a group there is a pause followed by a large beat, which (as shown in the diagram, Fig. 6) is due to the stimulus entering the ventricle in the normal way.

(d) *The Output of the Ventricle in Auricular Fibrillation.*

The ventricular beat in auricular fibrillation is started by a stimulus entering by the auriculo-ventricular bundle, and so we would expect a normal and efficient beat. Apparently

when the rate is infrequent the beat may be efficient, but when the rate is increased the beats tend to become less efficient in a curious manner. When the rate is moderate or slow the rhythm is irregular and there is often a distinct relation between the size of the beat and the preceding pause. But with increase of rate this relationship may be lost, and we have beats of various sizes without any relation to the duration of the preceding pause. This is brought out in Fig. 7, which shows the features characteristic of auricular fibrillation—irregularity in force and rhythm, with the typical ventricular form of jugular pulse. The tracings sometimes

FIG. 5.—Tracings of the jugular and radial pulses showing the idio-ventricular rhythm. The jugular tracing shows the waves due to the auricle (a) occurring regularly unaffected by the rapid action of the ventricle—shown by the radial beats. There are two groups of these idio-ventricular beats separated by two normal beats of the heart. (See diagram, Fig. 6.)

FIG. 6.—Diagram of Fig. 5 showing the relation of the auricle to the ventricle. The auricular and ventricular beats pursue independent rhythms except when the radial beats are large, and the diagram shows that the stimulus passes the a-c space and stimulates the ventricle.

have a superficial resemblance to those of the idio-ventricular rhythm, but there is no pause before the big radial beat, and there is no evidence of an auricular contraction preceding it. Moreover, it must be borne in mind that the stimulus for contraction in the idio-ventricular rhythm arises in the ventricle, while in auricular fibrillation the stimulus enters by the auriculo-ventricular bundle.

The Interpretation of the Radial Tracing in Auricular Fibrillation.

This lack of correspondence between the size of beat and preceding pause seems to be peculiar to this abnormal rhythm. It is possible that the same influence is present in auricular flutter, but that awaits further investigation. At one time I

suspected that the small beats might be due to ventricular extra-systoles, but the electro-cardiograph has shown that this is not the case. The only explanation seems to be that the variation in the size of the radial beats is due to differences in the contraction of the muscle cells of the ventricle. Probably they do not all contract at the same time—the varying size of the beat being due to the variation in the number of cells stimulated to contract.

In the patient from whom Fig. 7 was obtained the rhythm of the ventricle would suddenly pass from fibrillation to the normal, and the radial pulse would show the character

of a good-sized regular pulse indicative of a good acting ventricle. In considering the reason for the peculiar effect one can only infer that there was some difference in the nature of the stimulus which entered the ventricle, and it is therefore necessary to inquire into the nature of the stimulus to see if it be the same in auricular fibrillation as in the normal rhythm.

The Effect of Auricular Fibrillation and Flutter on the Auriculo-ventricular Node and Bundle.

When the auricle is fibrillating it has been reasoned that each muscle cell throws out a stimulus in its contraction, so that there is an incessant shower thrown upon the auriculo-ventricular node. How many of these pass depends on the susceptibility of the node, and this is estimated by the number of ventricular responses. When the ventricular rate

FIG. 7.—Simultaneous tracings of the radial and jugular pulses. The jugular pulse (a) is of the ventricular type. The beats in the radial are very unequal, and there is no constant relation between the size of the beat and the preceding pause—a large beat sometimes following a short pause and vice versa. This kind of irregularity with a want of relation between the size of beat and the length of the preceding pause occurs only in auricular fibrillation.

is slow it is inferred that the auriculo-ventricular node is less susceptible to stimulation. When the rate is increased in frequency it is assumed that the auriculo-ventricular node is more susceptible. But there is more in the matter than that.

We note such facts as these. When bodily effort is made the ventricular contractions are more numerous than when the rhythm is normal. Thus a patient at rest with auricular fibrillation may have a ventricular rate of 70. On moderate effort it may readily rise to 130 to 150 beats per minute—the same effort raising a normal heart only 10 to 15 beats.

While there is this suggestion of undue susceptibility in a positive sense, we have more convincing evidence of an undue susceptibility in the contrary sense. A patient with a normal rhythm but with a slight delay in the passage of the stimulus from auricle to ventricle, as shown by an abnormally wide a-c interval, developed auricular fibrillation. His ventricular rate with the normal rhythm was wonderfully uniform, about 60 beats per minute. With the onset of auricular fibrillation it fell to 40 beats per minute.

The Effect of Digitalis.

The most striking evidence of a difference in the nature of the stimulus is seen in the action of digitalis. The slowing that takes place in auricular fibrillation is much greater than can be produced in patients with a normal rhythm. Not infrequently, after a few doses, the rate would fall from 130 to 50 or 40 beats per minute. When the drug was stopped, in a few days the rate would rise again to 130.

The most dramatic evidence of the effect of digitalis is seen in certain cases of auricular flutter.

In some patients with this condition digitalis speedily causes a great fall in the ventricular rate, accompanied evidently with the passage of the auricular flutter into auricular fibrillation. The record in Fig. 8 shows a pulse or ventricular rate of 140 and an auricular rate of 280. After 1 drachm of tincture of digitalis taken for five days the pulse rate fell to 40 beats per minute, as in Fig. 9, and the rhythm had altered to auricular fibrillation, as shown by the jugular pulse. On the sixth day, periods of

the normal rhythm with a rate of 70 per minute (Fig. 10) varied with periods of auricular fibrillation with a ventricular rate of 40 (Fig. 9). It is manifest that the slow ventricular rate is not due to heart-block, for in the periods of the normal rhythm the stimulus was conducted at the rate of 70 per minute, while during the auricular fibrillation it was conducted at the rate of 40 per minute. Moreover, the a-c interval in Fig. 10 indicates a normal state of the conducting system (auriculo-ventricular node and bundle).

FIG. 8.—Tracing of the jugular and radial pulses during auricular flutter. (Auricular rate, 280; ventricular, 140.) The reason for the varying height of the a wave is that every second auricular contraction falls during ventricular systole, so that more blood is thrown back into the veins, and the a waves are therefore larger.

FIG. 9.—Tracing of the jugular and radial pulses from the same patient as Fig. 8 after digitalis. Auricular fibrillation is present, and the ventricular rate is 40 per minute.

FIG. 10.—Tracings showing the normal rhythm, which varied with auricular fibrillation, as shown in Fig. 9. The heart rate is 70 per minute, and the a-c interval normal.

was very ill, with breathlessness and pain on exertion. Fig. 5 is a tracing typical of the radial pulse before the administration of digitalis. The response to the drug was very speedy, as after 3 drachms of the tincture the pulse became much slower and at times regular. This effect is seen in Fig. 11. At times the ventricle responds to each auricular beat, as in the first part of this tracing, while in the latter part of the tracing there is one radial beat to two auricular beats. This is due to the occurrence of ventricular extra-systoles so weak that they failed to produce a radial beat.

The digitalis was stopped, and in a few days the heart had increased in rate and resumed all the characters shown in Fig. 5, and the patient felt very poorly. The resumption

FIG. 11.—Shows the effect of digitalis on the idio-ventricular rhythm. The pulse was very irregular, as in Fig. 5. Digitalis caused the resumption of the first five beats of this tracing; the rate is halved in the latter part of the tracing, which fail to affect the radial pulse. The character of the electro-cardiogram of the pulse in the latter part of the tracing is seen in Fig. 3.

of the digitalis had again the effect described, and he was told to continue the drug. Seen a year later, he was wonderfully well and had got so used to the digitalis that he could regulate the dose according to his necessity.

It is very likely that the effect of digitalis is the same in the fibrillating auricle as it is in the idio-ventricular rhythm. In both instances the auricle and ventricle have escaped from control of the conducting system, and a condition which is

susceptible to the influence of digitalis has been produced. Whether that is brought about by the direct influence of the drug modifying the stimulus or acting upon the muscle cells, or indirectly through the vagus, is not clear, but is a subject which awaits further investigation.

It is rare to get this form of idio-ventricular rhythm so persistent. In most of my cases it was transitory. In one other case I got a similar effect, but my opportunities were not sufficient for full observation. Dr. John Parkinson tells me that in one of his cases where this rhythm was persistent digitalis, though given in full doses, was without effect.

The Output of the Ventricle in Partial Heart-Block.

Further evidence of the difference between the two kinds of stimuli is found in what happens in partial heart-block. Here the bundle is damaged, so that the fibres are reduced in number, and the stimulus has a difficulty in passing from auricle to ventricle. However extreme the damage may be, and however weak the stimulus which manages to get through, the resultant contraction of the ventricle is always full and complete. In Fig. 12, where there is, as a rule, but one contraction of the ventricle to two contractions of the auricle, the radial beat is large and effective. In one instance the stimulus of the second auricular beat after some difficulty (as shown by the wide *a-c* interval) did get through to the ventricle, and here an efficient beat follows.

The inference from these facts is that a stimulus weakened in passing through the conducting system, on reaching the ventricle, gives rise to an effective ventricular systole, in contrast to the stimulus arising in the contracting system, as in auricular fibrillation, where the stimulus may not provoke a full systole.

The Different Origins of the Stimuli.

The normal stimulus which arises in the sino-auricular node and passes by the auriculo-ventricular node and bundle to the ventricle is a stimulus of a peculiar kind which arises in cells evolved for this particular purpose. The stimulus which arises in auricular fibrillation is produced by cells which were not evolved for this purpose, the stimulus being merely incidental to the contraction of the muscle cells. It is not likely that the same character of stimulus would be produced by cells evolved for the special purpose and by cells evolved for a totally different purpose.

The stimulus which arises in the conducting system apart from the sino-auricular node—that is, in the auricle and auriculo-ventricular node and bundle—is of the same quality as that which arises in the sino-auricular node. We can therefore recognize two kinds of stimuli: (1) a stimulus A, which arises in the conducting system, and (2) a stimulus B, which arises in the contracting system.

Is the Difference in the Stimuli one of Quality or one of Strength?

Although it may seem that the difference between the two kinds of stimuli is one of strength, yet there are certain reasons which suggest that the difference is one of quality. We have seen, for instance, the peculiar effect of the stimulus on the contraction of the ventricle in auricular fibrillation. This peculiarity is more likely to be due to the quality of the stimulus than to its strength, for the presumably weak stimulus which reaches the ventricle in partial heart-block gives rise to an effective ventricular systole.

The suggestion that the quality of the stimulus is different when it arises in the Purkinje fibres in the ventricle from that when it arises in the muscle cells of the ventricle may account for some curious differences in other abnormal rhythms, as in auricular flutter, extra-systoles, and the idio-ventricular rhythm.

This presentation of the subject is of very real importance for the practice of medicine. The pulse rate and the character of the pulse are among the most instructive signs the doctor uses in estimating a patient's condition. The nature of pulse variations, even with the normal rhythm, is

still imperfectly understood, and, as a consequence, only a small part of the information which they are capable of yielding is available. In the foregoing description some light is thrown upon the variations in rate and character which are due to abnormal rhythms, and we get a little nearer to understanding the action of digitalis, in that a factor hitherto unsuspected has been revealed. This aspect of the subject raises other questions, such as the nature of the stimulus in other abnormal rhythms—auricular flutter, the extra-systole, the idio-ventricular rhythm, etc. It also involves the question of stimulus conduction by nerves and the Purkinje cells. Can they convey and propagate from cell to cell stimuli of different qualities? The muscle cell to muscle cell stimulation in auricular fibrillation raises the question whether such intercellular stimulation occurs in other organs.

Summary of the Difference in the Heart's Contraction arising in the Conducting and Contracting Systems.

1. The stimulus for the normal rhythm of the heart arises in tissue specially evolved for the purpose. The stimulus in auricular fibrillation arises in tissue specially evolved for contraction, the stimulus production being merely an incident in the contraction.
2. There is a remarkable difference between the rhythms which arise in the conducting and contracting systems of the heart, due to the difference in the stimuli. These differences are shown especially in the response of the ventricle. The ventricular

systole in the normal rhythm, as well as in those rhythms arising in any part of the conducting system, is complete and effective.

3. The ventricular systole, when the stimulus arises in the muscle cells of the auricle, is often partial and ineffective, and when it arises in the muscle cells of the ventricle it is always ineffective.
4. When the contraction starts in the muscle cells of the auricle, as in auricular fibrillation, the stimulus which arises is much more sensitive to agents which favour or retard its passage to the ventricle.
5. The effect of digitalis is strikingly different, it having a far greater effect on auricular fibrillation and flutter and on the idio-ventricular rhythm than on any rhythm arising in the conducting system.

THE VALUE OF THE COMPLEMENT FIXATION TEST IN THE EXCLUSION OF ACTIVE PULMONARY TUBERCULOSIS.

BY

A. LISLE PUNCH, M.B.LOND., M.R.C.P.LOND.,
ASSISTANT PHYSICIAN, BROMPTON HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST; PHYSICIAN TO OUT-PATIENTS, ROYAL NORTHERN HOSPITAL;

AND

A. HOPE GOSSE, M.D.CANTAB., M.R.C.P.LOND.,
PHYSICIAN, BROMPTON HOSPITAL; PHYSICIAN TO OUT-PATIENTS, ST. MARY'S HOSPITAL.

A METHOD of performing the complement fixation test as a means of diagnosis in pulmonary tuberculosis has been published¹ by one of us (A. L. P.). By this method a positive result has been obtained in at least 98 per cent. of cases of definite pulmonary tuberculosis, while 140 cases selected as non-tuberculous controls gave a negative result in 137.

In all, the test has been performed in approximately 1,100 pulmonary cases or controls. Of these some 260 were definite cases of pulmonary tuberculosis, the criterion of a definite case being the undoubted presence of tubercle bacilli in the sputum. All save five of these gave a positive result. Of the five which gave a negative result three subsequently gave a positive. We do not propose here to enter into a discussion

of the possible explanation of those negative results, but we may mention in passing that we have formed the opinion that a negative result may occasionally be obtained in very acute cases of pulmonary tuberculosis due to the shortness of the interval between the invasion of the body by the tubercle bacillus and the onset of symptoms. Except in these rare cases the results of the test would suggest that a positive reaction is obtained by the time the infection gives rise to symptoms.

Some 140 presumably healthy people or patients suffering from non-tuberculous diseases were taken as negative controls. Three gave a positive result. These three cases have been considered in a previous publication. It is sufficient to mention here that in one definite evidence of enlarged, presumably tuberculous, glands in the neck was subsequently discovered; in another, on more careful examination, it was impossible definitely to exclude a tuberculous lesion in the lungs; while in the third no evidence of tuberculosis could be discovered. Of the remaining 700 cases some 220 gave a positive result and some 480 gave a negative. These were doubtful cases clinically, so that no definite conclusion could be drawn from them. All that could be said at the time without later investigation was that there seemed to be a reasonable correspondence between the clinical condition on the one hand and the negative or positive result on the other.

In many of the cases which gave a positive result the accuracy of the test has been proved by the finding at a later date of tubercle bacilli for the first time in the sputum, but it is not our intention to deal in this paper with the complement fixation positive cases.

The proof that cases giving a negative result are free from active pulmonary tuberculosis is a more difficult matter. It is only by the lapse of time that the practical proof of this contention can be firmly established.

It would be a very difficult matter to follow up all 480 of these cases, nor is it necessary in order to estimate the value of the test to attempt it. What is true of 50 unselected cases can be taken as approximately true of 500. Some 250 of these negative cases were at the time examined clinically by one or the other of us. Many of them have been examined by us at a later date. We only know of two cases of our own in which the test proved to be unreliable by the finding at a later date of tubercle bacilli in the sputum. Of the remaining 220 cases and our colleagues or other medical men, we know of three in which the test proved to be wrong by the finding of tubercle bacilli in the sputum. These three cases, with the two just mentioned, are the five cases referred to above. One was Sir John Broadbent's case and two were Professor Langmead's cases. If there are any other cases amongst these 480 in which the test has been proved to be unreliable by the finding of tubercle bacilli in the sputum we are not aware of them; and we may mention that we have been able to follow their course in a large number. We exclude a series of 50 cases which have been dealt with fully in a previous publication.

The ultimate practical proof of the entire freedom from active pulmonary tuberculosis is the lapse of time, and we have taken an unselected series of fifty of our own cases in which the test was performed in 1920 with a negative result, and where possible repeated it from ten to twenty months later. A similar result was obtained in all except one. These cases were all patients at the Brompton Hospital in whom for various reasons pulmonary tuberculosis had been suspected, and acted on it, that there was no active pulmonary tuberculosis. When the test was repeated from ten to twenty months later the greatest care was taken to have all bloods numbered by a third person, and included in series with known tuberculous bloods and unknown bloods, and the clinical condition handed to him. Thus if there should have been any doubt as to unconscious bias in the reading at the first test the numbering of the bloods at the second and the similar results amply prove the absence of bias at either.

Notes of Cases.

The clinical notes, taken before the tests were done, have been extracted, and as given below must serve as the evidence that we were dealing, in all the twenty cases, with suspicious cases of pulmonary tuberculosis.

* The authors originally forwarded fifty cases, reported as those here printed. At our request they have consented, in order to save space, to the reproduction of the first twenty only. The reports of all the fifty cases presented a great similarity, and the twenty here given are a fair sample.

No. 1.—E. D. Haemoptysis, a teaspoonful on several occasions in previous three months. Loss of weight; weight 6 st. 2 lb. Sputum negative. Complement fixation test negative on May 31st, 1920. Re-examination: Feels better; slight cough and sputum; no crepitations; weight 7 st. No haemoptysis lately. Complement fixation test negative on April 22nd, 1921.

No. 2.—J. F. Complaints of cough, sputum, night sweats; no crepitations; weight 9 st. 10 lb. Sputum said to have been positive once in 1919; negative since. Complement fixation test negative on June 4th, 1920. Re-examination: "Feeling fine." No cough, no sputum, no night sweats, no haemoptysis; no crepitations; weight 9 st. 10 lb. Complement fixation test negative on April 30th, 1921.

No. 3.—T. Haemoptysis streaks three weeks before; cough, sputum, and slight night sweats. Sputum three times negative. Dullness and crepitations at right base. Complement fixation test negative on June 16th, 1920. Re-examination: Cough, sputum, and dyspnoea, especially on exertion. Signs as before. Sputum negative. Diagnosis, fibrosis of right lung. Complement fixation test negative on May 6th, 1921.

No. 4.—I. B. Sent up for diagnosis. Pulmonary tuberculosis suspected. Pain in right chest; wasting. Pleurisy in February, 1920. No crepitations. Complement fixation test negative on June 18th, 1920. Re-examination: Feels quite fit; no symptoms. Complement fixation test negative on May 26th, 1921.

No. 5.—R. G. Cough; sputum copious; dyspnoea. Temperature 102.4°. Weight 9 st. 8 lb. Physical signs of cavity at right apex. Sputum repeatedly negative. Complement fixation test negative on June 18th, 1920. Re-examination: Symptoms and signs as before; weight 10 st. 2 lb. Sputum still negative. Diagnosis, apical bronchiectasis. Complement fixation test negative on May 20th, 1921.

No. 6.—R. Cough; pain in right chest; plenrisy right base. Father, sister, and brother all stated to have died of pulmonary tuberculosis in previous three years. No sputum available. Complement fixation test negative on June 2nd, 1920. Re-examination: No symptoms now; no crepitations. Complement fixation test negative on April 30th, 1921.

No. 7.—W. O. E. Haemoptysis half a pint in November, 1917; loss of weight. Been to a sanatorium. Colour in sputum forthright before. No crepitations. Sputum negative. Weight 8 st. 8 lb. Complement fixation test negative on June 14th, 1921. Re-examination: Some cough and sputum; negative for tubercle bacilli. No further haemoptysis; no crepitations. Weight 8 st. 5 lb. Complement fixation test negative on May 1st, 1921.

No. 8.—J. J. T. Cough; pain in left chest. In military hospital 1916. "T.B. lung." Weight 9 st. 1 lb. Clubbing of fingers. Physical signs of unilateral fibrosis of left lung. Re-examination: Fixation test negative on October 30th, 1920. Re-examination: Physical signs as before. No tubercle bacilli in sputum. Weight 9 st. Complement fixation test negative on May 4th, 1921.

No. 9.—F. F. Cough; sputum. Temperature 99.6°; night sweats. Sputum negative. No crepitations. Complement fixation test negative on June 24th, 1920. Re-examination: Cough and morning sputum; no crepitations. No sputum sent for examination. Diagnosis, chronic bronchitis. Complement fixation test negative on May 16th, 1921.

No. 10.—H. V. Cough; sputum; coarse râles over lungs. Weight 9 st. 1 lb. Sputum stated to have been positive once—in July, 1919. Frequent attacks of asthma. Complement fixation test negative on May 26th, 1920. Re-examination: Has been under treatment since for asthma only. Chest dry on examination. Weight 9 st. 6 lb. Sputum negative. Complement fixation test negative on May 26th, 1921.

No. 11.—A. K. No cough. Patient stated she had coughed up one pint of blood a month before. Complement fixation test negative on June 29th, 1920. Re-examination: While an in-patient was diagnosed as gastric ulcer. No chest symptoms. Complement fixation test negative on May 28th, 1921.

No. 12.—J. H. War pensioner. Cough; slight sputum. Tubercle bacilli reported once only in sputum, December, 1919. Sputum negative since. No crepitations; weight 8 st. 7 lb. Complement fixation test negative on August 5th, 1920. Re-examination: Feels well; no cough; no sputum. Weight 8 st. 7 lb. Complement fixation test negative on June 1st, 1921.

No. 13.—W. E. W. Weakness; cough. Streaks of haemoptysis two years before. Coarse râles in both lungs. Weight 8 st. 13 lb. Sputum negative. Complement fixation test negative on December 1st, 1920. Re-examination: Cough and sputum present; no tubercle bacilli in sputum. Coarse râles in chest. Weight 9 st. 7 lb. Complement fixation test negative on June 1st, 1921.

No. 14.—E. S. Cough; sputum. Haemoptysis in streaks in past three weeks. Temperature 99.4°. No crepitations. Complement fixation test negative on July 8th, 1920. Re-examination: No more haemoptysis; no crepitations. Complement fixation test negative on June 2nd, 1921.

No. 15.—E. B. Cough; sputum. Haemoptysis (slight) three weeks before. Temperature 99°; pulso 104. No crepitations. The complement fixation test was negative on August 19th, 1920. Re-examination: Patient replied fourteen months later: "I am glad to say I am keeping in the best of health, and have done so for a long time past now; had I felt in any way bad I should have come up before."

No. 16.—L., aged 20. Pain in chest; cough. Temperature 101° each night for three weeks. Signs of pleural effusion; confirmed by exploratory needle. Complement fixation test negative on November 2nd, 1920. Post-mortem examination six weeks after above test showed malignant growth in left lung and effusion into pleural cavity. Primary growth in ovary.

No. 17.—G. H., war pensioner. Cough; sputum; pain in chest. Stated he coughed up four pints of blood in April, 1920. Weight 8 st. 3 lb. Sputum negative. No crepitations. Complement fixation test negative on December 1st, 1920. Re-examination: Pain in abdomen after food. No crepitations. Weight 8 st. 4 lb. Sputum negative. Complement fixation test negative on October 5th, 1921.

No. 18.—S. Cough; sputum; pain in back. Debility six months. Sputum negative four times. No crepitations. Complement fixation test negative on July 14th, 1920. Re-examination: No fresh symptoms. Has been at work since last seen. Complement fixation test weakly positive on June 4th, 1921. Examination of sputum seven months later positive. Brother died of pulmonary tuberculosis in October, 1921. Contact. Complement fixation test strongly positive on February 11th, 1922.

No. 19.—E. W. Cough; sputum. Haemoptysis (streaks) in May, 1920. Loss of weight; feels ill. Temperature 99.6°. Weight 8 st. 5 lb. Sputum negative. Complement fixation test negative on September 27th, 1920. Re-examination: Feels well; no cough. Weight 8 st. 5 lb. Temperature 98°. No crepitations. Complement fixation test negative on November 8th, 1921.

No. 20.—T. P. Cough; sputum; dyspnoea. Weight 8 st. 4 lb. No crepitations. Sputum negative. Complement fixation test negative on September 24th, 1920. Re-examination: Feels better; still has dyspnoea. Weight 9 st. 3 lb. No crepitations. Complement fixation test negative on April 22nd, 1921.

Comments.

A study of the above cases will show that the clinical condition at the time of the first test justified a strong suspicion of pulmonary tuberculosis. In all of them some combination of cough, sputum, fatigue, loss of weight, pyrexia, haemoptysis, and pain in the chest was present—in fact all the common symptoms of pulmonary tuberculosis. The frequency of haemoptysis is a striking feature.

A study of the re-examination notes will show an absence of any further evidence of the disease some ten to twenty months later. The too frequent absence of sputum reports when the patients were re-examined is due to the absence of any sputum. In no case did apical crepitations appear at the later examination, and almost all cases were examined by post-graduates as well as the writers. No. 18 had a weak positive complement fixation test at the re-examination, and the sputum was found positive seven months after the positive complement fixation test; but he had been a "contact" till four months after the second test was taken when his brother died, so the infection may have occurred between the first and second tests. Many patients had regained their normal health, some had improved, and others were unchanged. Two of the fifty cases died, and post-mortem examinations showed malignant growths of the lung or pleura as the cause of death. After the lapse of ten to twenty months, or even longer forty-nine had not developed any definite evidence of pulmonary tuberculosis, nor, with a few exceptions, were they even under treatment.

It is the absence of the development of any more definite evidence of tuberculous infection in all but one of these suspicious cases in the course of ten to twenty months afterwards that would appear to us to offer striking evidence in favour of the accuracy of the test and to demonstrate its value in the exclusion of active pulmonary tuberculosis.

We wish to thank the Lady Almoner of the Brompton Hospital for her valuable help in tracing the patients.

The laboratory work has been done in the Institute of Pathology and Research, St. Mary's Hospital, under a grant from the Medical Research Council.

At a meeting of the Manchester Pathological Society on February 8th, with Mr. Howson Ray in the chair, Dr. J. A. Murray, Director of the Cancer Research Fund, demonstrated the pathological anatomy of experimentally induced squamous carcinomata of the skin of the mouse following repeated and continued application of coal tar. Lantern slides were shown illustrating the growth of the tumours, their metastases and dissemination, and the invasion of the subjacent tissues. Reference was made to the application of antoplastic implantation of tumour fragments to bring out the powers of growth of the altered epithelium when removed from the direct irritating influence of the tar and of bacterial infection. By this method of artificial metastasis it was possible to demonstrate the malignancy of growths at a very early period. The relative advantages were discussed of other successful methods of inducing cancerous changes.

EVIDENCE OF PANCREATIC DISORDER IN RICKETS.

BY

E. C. DODDS, M.R.C.S., L.R.C.P.,

CHEMICAL PATHOLOGIST AND LECTURER IN BIOCHEMISTRY, MIDDLESEX HOSPITAL; PATHOLOGIST TO THE ROYAL NATIONAL ORTHOPAEDIC HOSPITAL.

(From the Bland-Sutton Institute of Pathology.)

MANY observers have been working on the factors concerned in the production of rickets, and recently special prominence has been given to the view that the problem is intimately bound up with the question of diet, more especially with the amount and quality of the fats. It is urged also that carbohydrates play an important part, but as to the explanation of these two facts there is still considerable difference of opinion.

The well-known vitamin deficiency theory ascribes the production of rickets to a lack of the vitamin A, which is fat-soluble; but with regard to the carbohydrate part of the problem, no observer seems to have given a satisfactory explanation. In this communication the importance of both fats and carbohydrates is taken into account, but the conclusions to be drawn from the investigations made point in a different direction. As a result of the examination of cases of acute rickets in children, distinct evidence was found of pancreatic disorder, as determined by an increase (1) in urinary diastase, and (2) in faecal fat content.

1. The Diastatic Power of the Urine.

By means of its diastatic enzyme normal urine is able to hydrolyse starch solution to a mixture of products which give no colour with iodine solution. Wohlgenuth expressed this property of urine quantitatively by means of "units," the number of units of diastase being given by the number of cubic centimetres of 0.1 per cent. starch solution digested by 1 c.cm. of urine.

Method.

The usual method is to put up a series of test tubes, each being filled as follows:

Test tubes:	1.	2.	3.	4.	5.	6.	7.	8.	9.	10.	11.	12.
Starch 0.1%	2 c.cm.	2 c.cm.	2 c.cm.	2 c.cm.	2 c.cm.	2 c.cm.	2 c.cm.	2 c.cm.	2 c.cm.	2 c.cm.	2 c.cm.	2 c.cm.
Urine	0.3 c.cm.	0.2 c.cm.	0.1 c.cm.	0.09 c.cm.	0.08 c.cm.	0.07 c.cm.	0.06 c.cm.	0.05 c.cm.	0.04 c.cm.	0.03 c.cm.	0.02 c.cm.	0.01 c.cm.
Saline	0.7 c.cm.	0.8 c.cm.	0.9 c.cm.	1 c.cm.	1 c.cm.	1 c.cm.	1 c.cm.	1 c.cm.	1 c.cm.	1 c.cm.	1 c.cm.	1 c.cm.

The starch solution is put in first, then the urine, and the saline is run in last, in order to wash the first two down to the bottom of the tube.

The tubes are incubated in a water bath at 37°C. for half an hour, are then cooled under tap water, and enough N/50 iodine solution to produce a permanent colour is added to each tube. The tube immediately preceding one with a mauve tint is taken as that in which the 2 c.cm. of starch solution is just digested by the urine. Suppose 0.1 c.cm. of urine digests 2 c.cm. of starch solution, then 1 c.cm. of urine would digest 20 c.cm. of starch solution—that is, there would be 20 units of diastase present.

Towards the end of this series of diastase reactions, I modified the original method so as to take into account the hydrogen-ion concentration of the urine. The diastatic enzyme works best at a

pH 6.1 (Michaelis), and since the pH of the urine is usually between pH 4.5 to pH 7 it is of the urine is pH 6.1, the diastatic

power will be decreased. The newer technique is to bring the urine's hydrogen-ion concentration to approximately pH 6.1 by diluting it with a buffer solution of phosphates and then determining the diastase as in the ordinary method. A description of this method will be given elsewhere, but it should be pointed out that it can only increase a low reading of the ordinary method, and can never decrease it.

The normal number of diastatic units in urine lies between 6 and 30. Any increase is said to indicate pancreatitis, with the possible exception of cases of eclampsia, in which the diastatic power is said to be high.

In Table I are given the figures from a series of cases of acute rickets; all are high enough to warrant a diagnosis of pancreatitis. The mean of 17 cases is 154 diastatic units.

These results were controlled by the examination of a series of normal children of about the same age as the rickety cases; as will be seen from Table III, the results were all low. As some observers maintain that there is a general infection in rickets, series of septic cases showing no rickets, and with and without fever, were examined (Table III). It was also thought advisable to make control observations on a series of cases where there was bone erosion (Table III).

All these cases gave low results. The diastase was found to be higher than normal in three cases of acute osteomyelitis—namely, 66, 50, 66 units—but this was very much below the mean of the rickety cases, which was 154. Convalescent cases of rickets, as will be seen from Table II, did not show this high diastatic power. They gave an average of 14.5 units.

TABLE I.—*Acute Rickets (17 Cases).*

Age.	Sex.	Diastase.	Fat in Faeces per Cent.	Age.	Sex.	Diastase.	Fat in Faeces per Cent.
2	M	100	65	2	F	150	78
3	M	200	80	4½	F	70	50
3	M	200	89	2	M	200	90
9½	F	200	50	9½	F	150	79
1	M	100	70	1	M	100	69
2	M	150	80	1½	F	100	60
2½	M	200	60	2	M	200	65
4	F	150	70	4	M	150	78
3	M	200	80				

Total diastatic units ... 2320. Mean ... 154.
Total fat in faeces per cent. ... 1273. Mean ... 73.

TABLE II.—*Rickets, Subacute or after Treatment (6 Cases).*

Diastase.	Fat in Faeces per Cent.	Remarks.
10	20	No. 1 in Table I, six months after.
25	25	No. 2 in Table I, six months after.
33	56	No. 3 in Table I, three months after.

7	20	No. 5 in Table I, two months after.
7	23	No. 7 in Table I, twelve months after.
22	38	After six months' treatment.
20	30	After three months' treatment.

TABLE III.—*Controls for Diastase and Fat in Faeces.*

Condition of Cases.	No. of Cases Investigated.	Average Diastase.	Average Fat in Faeces per Cent.
Normal children ...	10	16	20
Septic cases, with no fever ...	6	20	22
Septic cases, with fever ...	7	13	—
Bone erosion, mainly new growth involving bone ...	9	10	—

2. The Fat Content of the Faeces.

Normal dry faeces contain 25 per cent. of fat by weight at a maximum. Any increase above this is usually regarded as pathological. If the increase consists mainly of unsplitted fats, it is assumed that the pancreatic lipase is at fault, and, if pancreatitis is suspected. It is, of course, essential that there be no great increase in the fat diet, otherwise the high faecal fat content might be explained by a simple passage through the intestines of an excess of fat in the diet.

The rickety cases investigated were on ordinary diet, and the faeces were collected and dried very carefully. The fat content was then estimated by means of the Schmidt-Werner process. Table I shows that in all the faeces obtained from cases of acute rickets the fat content was greatly increased—a mean of 75 per cent. against the normal of 25 per cent.

Controls.—This result was controlled by examining a series of non-rickety children of about the same age and on the same diet; it will be seen from Table III that all the readings were low—an average of 20 per cent. As in the case of the diastase reactions, convalescent cases did not show this high faecal fat content (Table II).

3. Acidosis in Rickets.

The urine of 10 cases of acute rickets was examined for acetone bodies, and it was found that 9 cases gave quite a

strongly positive Rothera's test. The other case only gave a very faint pink colour. Of the 9 cases, 6 gave a very faint ferric chloride test for aceto-acetic acid, but both the Rothera and ferric chloride tests became negative after a few weeks of treatment.

In a recent article Dr. Amy Hodgson² reported the results of a detailed analysis of the urine of 13 children with active rickets; she found marked evidence of an acidosis, as determined by the ammonia ratio—that is:

NH₃ per cent.
N₂ per cent.

The mean of her 13 cases was 14.3 per cent., as compared with 6.2 per cent. for a series of normal healthy children.

Without entering into a discussion of the exact pathology of the acidosis frequently found in children, it seems clear from these observations that rickets must be added to the list of diseases in which it occurs.

Consideration of Results.

The results obtained—namely, a high diastatic power of the urine and a high faecal fat content—suggest a diagnosis of a pancreatic lesion. The large amount of unsplitted fat in the faeces shows that it must be associated with reduced secretion of pancreatic juice. Exactly what bearing these facts have upon the pathology of rickets it is difficult at first sight to say.

It has been taught for some long time past that the fatty acids, when liberated from the neutral fats by the action of the pancreatic lipase, form soaps with the metallic bases, especially with calcium; the resulting calcium soap, being soluble in bile, is absorbed. If this is the most important mode of calcium absorption, the importance of inadequate pancreatic secretion at once becomes obvious, because there would be poor fat digestion and, consequently, poor production of fatty acids. This would lead to deficient calcium absorption, and therefore to calcium starvation, which has been stated to occur in rickets.

This theory is being tested by noticing the effect of fatty acids on calcium absorption, both in rickety and in normal children. The experiments are in too early a stage yet to warrant a definite statement being made. Since there is a deficiency of pancreatic secretion a new line of treatment suggests itself—namely, that of giving a pancreatic extract which contains lipase. A number of cases are now being treated with this extract in the hopes that it will digest fats in the intestine, and thereby give an adequate amount of free fatty acids for the absorption of calcium.

It is interesting to note that in Germany cases have been treated with calcium soaps of fatty acids.³ The scientific basis of this mode of treatment was not stated, but the views put forward in this paper seem to offer an explanation.

It is quite likely that this pancreatic lesion is the result of an intoxication, probably bacterial in origin. Investigations are now in progress to determine, if possible, the source of the intoxication and infection.

In conclusion, I have to express my thanks for much very valuable advice and criticism from Professor McIntosh and Dr. E. L. Kennaway, and also to acknowledge the kindness of the surgeons of the Royal National Orthopaedic Hospital for allowing me to investigate their cases.

Summary.

1. The diastatic power of the urine is greatly increased in rickets, the mean of 17 cases being 154.
2. The diastatic power falls to normal during convalescence.
3. The fat in the faeces is increased in rickets, the mean being 75 per cent., as compared with 20 per cent. for a series of non-rickety children.
4. From the above observations it is suggested that there is a pancreatic lesion in rickets, and a possible explanation of its bearing on the disease is given—namely, that there is a poor production of fatty acids, and consequently a poor absorption of calcium.
5. Attention is called to the acidosis of rickets.
6. In consideration of the above results cases of rickets are being treated with pancreatic extract containing lipase.

SOME OBSERVATIONS ON POST-ANAESTHETIC COMPLICATIONS.*

BY

G. F. R. SMITH, M.B., B.S. LOND., M.D. LIVER.,

HONORARY ANAESTHETIST TO THE ROYAL INFIRMARY, LIVERPOOL, ETC.

OBSERVATIONS have been made upon 571 cases of general anaesthesia, drawn from the Hospital for Women and the Royal Infirmary, Liverpool, attention being particularly focussed on three common post-operative complications—namely, chest trouble, flatulence, and vomiting. In the series there have been four deaths—one from operative shock, one from bronchopneumonia, one from acidosis, and one, which occurred on the fifth day after a laparotomy for inoperable carcinoma, may be laid to the door of both surgeon and anaesthetist, as there were some symptoms of acid intoxication.

Among the gynaecological cases there were 221 major abdominal and 220 minor vaginal operations. Warm ether, with where necessary a small addition of chloroform, was given to the former, and open ether to the latter. The chest complications for both classes of case amounted to 22—that is, 4.5 per cent.; serious trouble, such as bronchitis and bronchopneumonia (including the death already mentioned), occurred five times—1.1 per cent.; the remainder, coughs without physical signs, soon cleared up when a mixture containing calcium chloride and liquor-atropinæ was given. The major operations showed a morbidity of 7.5 per cent., and the minor of 2.2 per cent. I think it will be admitted that 1.1 per cent. of serious pulmonary disease after operation is low, and it may be attributed to the use of warmed ether vapour, as prior to its introduction at the Hospital for Women lung complications were considerably more frequent. It does not, however, entirely prevent the likelihood of bronchitis if given to a patient already suffering from a "cold," and where there is any acute catarrh of the respiratory tract a general anaesthetic, except for emergencies, is contraindicated, though I would add that in such cases chloroform is justifiable.

The usually accepted causes of ether bronchitis, such as septic mouth, draughts, chills from sweating, etc., are guarded against as much as possible, and all masks, gauze, and face pads are sterilized at the Hospital for Women, so it is difficult to account for this 4.5 per cent., but in 11 out of the 22 cases the following possible factors were noted: pre-operative cough, some cyanosis during part of the operation, prolonged operation, the patient required more than the usual amount of ether, light anaesthesia, and pulling on the peritoneum.

To illustrate the possibility of prophylaxis I would mention the case of a very stout woman, aged 36, who, after an operation for removal of both appendages, had considerable bronchitis for a week; two months later it was found necessary to perform a total hysterectomy, but after three days' preoperative treatment with the mixture already mentioned she recovered from the anaesthetic with neither cough nor vomiting. A further practical point is that when morphine is used along with atropine, 1/150 grain of the latter is sufficient to prevent salivation, and does not cause the irritating dryness of the mouth so frequently complained of after 1/100 grain.

Flatulence occurred twenty-four times in the series, which gives a percentage of 5.4, but here it must be noted that an important alteration in the treatment prior to operation took place during the observations. To the first 266 cases 1 oz. of castor oil was given thirty-six hours before, an enema eight hours before, 1/4 grain morphine and 1/100 grain of atropine one hour before, and a very light liquid diet on the day preceding operation. Here the percentage of flatulence was 6. The following 175 cases were given castor oil as before, but the enema was omitted except for those requiring crucial repair, the dose of morphine was lessened to 1/6 grain, and a more generous diet allowed—ordinary food the previous day, and a breakfast of tea and toast, followed by oz. of syrup of glucose one hour before operation. Under his régime flatulence occurred in 4.5 per cent. only. It should, however, be added that the ward sister, without those most intelligent co-operation this note could not have been written, considers the improvement in this respect to have been greater than is shown by the figures, and her opinion is corroborated by a sister at the Royal Infirmary,

whose experience after a similar change in preparation is that "the patients are much less distended and uncomfortable."

Vomiting, the commonest and most distressing complication we have to deal with, was met with 91 times in 441 cases, major operations showing 27.6 per cent. and minor operations 12.7 per cent., the percentage in all cases being 20.1. These figures include all grades of vomiting, and require modification; 350 women were not sick at all, which I must confess surprised me; of the remainder, 52 (11.7 per cent.) only brought up a little mucus once or twice directly after return to the ward, 17 (3.8 per cent.) vomited several times; but were comfortable within six hours of the operation, and 32 (7.2 per cent.) continued to vomit for periods varying from ten hours to three days. Here the change in preparation caused disappointment, as the total vomiting percentage increased from 17.2 to 25.1 instead of showing the decrease which had been hoped for. There is, however, one scrap of comfort in that the increase occurred in the slight and moderate forms of sickness; the severe class showed a decrease from 6 to 3.4 per cent.

There is not time to analyse completely the 130 cases on which notes have been taken at the Royal Infirmary, but a comparison may be made, as both "open" and "close" methods of anaesthetization were in use. Where ether was given on an open mask vomiting took place in 51.2 per cent. of cases; in 5 per cent. it was of a serious nature; Ormsby's inhaler, on the other hand, only produced 32 per cent., but in 10 per cent. the sickness continued for more than six hours. This is contrary to the generally accepted belief that "open ether" causes less vomiting than "close," but it bears out the opinion of many anaesthetists that in the hands of an expert the despised bag has much to commend it.

Whether the increased percentage at the Royal Infirmary, where the figures are more than double those at the Hospital for Women (43.8 per cent. compared with 20.1 per cent.), is accounted for by the fact that at the former an enema is given and no aperient, or that the anaesthetics are largely given by the students, I am not prepared to say, but the difference is rather striking.

The morbidity rates disclosed by this series of observations are, it must be confessed, disappointing, but they are brought forward with the idea of interesting others enough to find some alteration of technique which will eliminate these three common sources of trouble and further improve what may be called the handmaiden of surgery.

May I close by expressing my thanks to Dr. Gemmell and Messrs. Bickersteth and Jeans, from whose clinics these few facts have been extracted.

THE DIAGNOSTIC VALUE OF THE PLANTAR EXTENSOR RESPONSE.

BY

E. L. FOX, M.D., M.R.C.P.,

PHYSICIAN TO THE SOUTH DEVON HOSPITAL.

From the time when this sign was first described by Babinski we have been taught and have reverently bowed the knee to its organic significance. From time to time some diffident suggestions have appeared that possibly it might be liable to variation, but I have never seen any definite statement impugning its reliability. I know the difficulty of sometimes obtaining it, especially if the foot is cold, but that its variability may be great at different times in the same patient I certainly had not seen before.

I have under my care, in the South Devon Hospital, a marine who was sent in by the pension authorities. He was first admitted in December, 1919, with a provisional diagnosis of spinal tumour.

He had over eighteen years' continuous service, with no history of any previous illness. His war service extended for nearly three years, with four months' service ashore at the Cameroons. He complained chiefly of intense pain in the back, with extreme rigidity of his legs which quite prevented him from walking. At night he frequently had "war dreams," in which he cried out and disturbed the ward.

The rigidity was very marked, and I could only flex his knees with the greatest difficulty. The patellar reflexes were very active; ankle clonus was present on both sides; the plantar response was always readily obtained, and was consistently extensor in type. He had anaesthesia extending equally and completely over both legs, but above that sensation

* Read at the Liverpool Medical Institution on October 27th, 1921.

was normal. He seemed to me to correspond fairly well with the cases of astasia one met with during the war.

He gradually recovered, and was discharged in June, 1920, for treatment and training at a convalescent camp. There he remained until one day he had a fall, when all his old symptoms reappeared, and in March, 1921, he was readmitted to the South Devon Hospital. His condition then was by no means so severe as when first seen. The rigidity, however, was still extreme, ankle clonus just as readily obtained, and the extensor response the same as before.

His recovery this time was very slow, and he has only just reached a condition in which he is nearly ready to resume training.

The extensor response for a long time never varied, then as the rigidity of the legs decreased it also became less marked; then it would be present on one side and not on the other; then it would be absent on both sides in the morning, returning if he was tired in the evening.

Treatment has not availed him much. Electricity in all forms failed to help him. Hot-air baths certainly seemed to benefit him, as the rigidity was less after them, and his recovery has been more rapid since they were started.

His war history was not beset with any startling incidents; the only event which has probably had some bearing on his disorder was that once whilst coaling at sea a friend of his had both legs badly crushed.

Meanwhile the man has been discharged by the pension authorities as suffering from disseminated sclerosis, which was neither caused nor aggravated by war service, and I feel that this has been brought about because at one time the plantar reflex could always be obtained, and was consistently extensor in type.

ENCEPHALITIS LETHARGICA AFFECTING THE NUCLEI OF THE MID-BRAIN IN AN UNUSUAL MANNER.

BY
WILLIAM CALWELL, M.D.,

PHYSICIAN TO THE ROYAL VICTORIA HOSPITAL, BELFAST.

THE following case is of interest, for though the symptoms were obscure it seems probable that the acute illness in June was an attack of encephalitis lethargica.

A married woman, aged 54, under the care of Dr. McDowell, Belfast, had been healthy and had a healthy family. About the end of June, 1921, she had an acute illness, of which the chief symptoms were vomiting, dirty tongue, etc. This condition lasted a fortnight, and at first no nerve signs were evident. She became weak, giddy, with indistinct vision, which, however, varied. The vomiting stopped, but when she tried to stand she felt giddy, as if falling forwards or backwards. On October 21st the general clinical examination revealed nothing abnormal: the urine was normal; there was no high blood pressure; she was perfectly intelligent, the motor and sensory systems were normal. She even sharp; had no difficulty in finding a word, but considerable difficulty in articulation; she had to force her words, and said "wor" for worse, and so that at times her speech was a little confused, sturred and clipped, and at other moments slightly jerky and nearly explosive. There was a want of tone in the feet of the muscles of the limbs, which hardly seemed to be accounted for by the confinement; the plantar reflexes were absent, the knee-jerks were present but not exaggerated; no other muscle jerks were elicited.

In regard to the eyes, there was a slight droop of both upper lids, but this was said to be natural; the left pupil was larger than the right; both reacted to light and to accommodation somewhat sluggishly. When she looked to the left there was lateral nystagmus, when to the right vertical nystagmus, somewhat slow in character. On November 9th, when she looked to the left, the nystagmus was also vertical; but on looking to the right and a little upward a fine rapid lateral nystagmus was visible. With the ophthalmoscope the discs were found to be normal, but a constant slow, vertical, fine nystagmus was seen. The iris did not show the local shadow reaction test.

Her hearing was perfect; she thought that she heard at times "too much," meaning that she heard what was not intended for her to hear. When she got up she had to hold on to something, like the foot of the bed, and have her other arm taken; deglutition was normal.

The most probable explanation, as has been said, would appear to be that the original attack was encephalitis lethargica. There were no signs of cerebral tumour; she presented no signs of vascular degeneration; syphilis may be excluded by her previous good health, her healthy family, and a negative Wassermann test (blood). The site of the lesion is localized; the cortex down to the internal capsule can be excluded, also the t.

nuclei in the roof of the mid-brain, with their intricate and complicated ramifications, possibly the red nucleus, and Deiters's nucleus in the medulla, are involved. The connexion between the tectum nuclei, the cerebellum, the vestibular nucleus and so with the semicircular canals, and the many tracts to the cord, would seem to explain the vertigo, the loss of tone of the muscles, the nystagmus of the bizarre type, the unequal pupils, and possibly the ptosis. The speech could be explained by the cerebellar asynergy, and as part of the loss of control of the muscles showing itself subjectively in the vertigo. If Deiters's nucleus be affected the nuclei of the nerves for the muscles of articulation are not far off.

We have an analogy in the condition left by encephalitis lethargica in the globus pallidus, simulating paralysis agitans. In both instances all the cells affected are of the motor type, and so follow the rule.

THE ANTISEPTIC PROPERTIES OF CYANINE DYES.*

BY
C. H. BROWNING, J. B. COHEN, AND R. GULBRÄNSSEN.

(From the Department of Organic Chemistry, Leeds University, and the Pathological Department of the University and Western Infirmary, Glasgow.)

THE group of compounds, a few of which form the subject of the present communication, are known as isocyanines and carbocyanines, and are prepared by condensing a mixture of quinoline or quinaldine alkyl iodide with a quinaldine alkyl iodide in presence of an alkali with or without formaldehyde. These substances are used as photographic sensitizers. Thus the isocyanine known by the trade name of "sensitol green" is produced by the condensation of quinoline methiodide with p-tolu-quinaldine methiodide. "Sensitol red" is produced similarly by the condensation of two molecules of quinaldine alkyl iodide with one of formaldehyde under the influence of alkali. According to Mills and Pope² the constitution of "sensitol red" is represented by the following formula:

To this group of compounds, which have been studied by Mills and Pope and Mills and Wishart,³ the generic name of "carbocyanine" has been given, whilst the "isocyanine" will be represented by the following general formula:

in which R stands for an alkyl group.

Antiseptic properties were determined, as previously described,¹ by adding to 1 c.cm. of culture medium varying amounts of the substances to be tested along with 0.1 c.cm. of a 1 in 1,000 dilution in saline of a twenty-four hour culture of the organisms (*Staphylococcus aureus* or *B. coli*) in peptone water. As test media (a) 0.7 per cent. peptone water with a PH value of about 7.2, and (b) undiluted ox serum (previously heated at 56° C.). The mixtures were then placed at 37° C. and were examined after forty-eight hours for the presence or absence of growth, which was determined in each instance by the appearance of turbidity in the fluid, and also by subculturing a loopful on agar.

The compounds tested were "sensitol red," "sensitol violet," and "sensitol green." These names do not describe the colour of the dyes, but the part of the spectrum to which a photographic plate is rendered specially sensitive after treatment with the compounds in question. Owing to the relative insolubility of sensitol red and sensitol green, stock solutions of 1/2 per cent. of the dyes in 50 per cent. alcohol were prepared, and these were further diluted with water as

*This work was carried out with the support of the Medical Research Council.

required. The following figures represent the general antiseptic values obtained in repeated tests:

Substance	Staphylococcus aureus in		B. coli in	
	Pentone Water.	Serum.	Pentone Water.	Serum.
Sensitol red	1:4,000,000 + 1:2,000,000 -	1:1,000,000 + 1:200,000 -	1:1,000 + ? -	1:10,000 + 1:2,000 -
Sensitol violet	1:100,000 + 1:10,000 -	1:40,000 + 1:10,000 -	1:1,000 + ? -	1:4,000 + (1:1,000 inhibition)
Sensitol green	1:400,000 + 1:200,000 -	1:1,000,000 + 1:100,000 -	1:10,000 + 1:5,000 -	1:50,000 + 1:10,000 -

* Precipitation of dye.

+ = Abundant growth visible to the naked eye.

- = Sterile, as shown by subculture.

Accordingly, the following conclusions may be drawn as regards the cyanine group of dyes, which, so far as we know, have not been examined hitherto for their antiseptic properties.

1. Certain of the cyanine dyes are extremely potent antiseptics—for example, sensitol red for staphylococci in watery medium.

2. Selective antiseptic action as between staphylococci and *B. coli* is exhibited to a higher degree by certain of these dyes—for example, sensitol red—than by any other compound hitherto investigated, the ratios of the sterilizing concentrations probably being greater than 2,000 to 1 (with crystal violet the ratio is 500 to 1).

3. Sensitol green is the most active of these dyes both in serum and watery medium for *B. coli*. Also, in the case of *B. coli* the antiseptic action in serum is more intense than in watery medium.

Observations on the toxicity of these compounds for mammalian tissues and on the action of further members of the series will be recorded later.

THE INTERPRETATION OF SYMPTOMS IN DISEASE OF THE CENTRAL NERVOUS SYSTEM.

ABSTRACT OF THE GOULSTONIAN LECTURES, DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS,

BY

ANTHONY FEILING, M.D., F.R.C.P.,

PHYSICIAN, HOSPITAL FOR THE BLIND AND PARALYSIS, LONDON.

LECTURE I.

THE lecturer introduced his subject by saying that in conversation with many doctors he had been struck by the lack of comprehension of those main principles of neurology which were so essential to any accurate diagnosis of disease of the central nervous system. There was here a gap in knowledge, the more remarkable when contrasted with the appreciation of the symptoms and signs of disease in other systems of the body. It could only proceed from some defect in teaching, and therefore he would attempt in these lectures, which were based upon the general experience and the painstaking observations of many workers, to give an epitome of the general principles of diagnosis and an interpretation of some of the more important and characteristic symptoms of disease of the central nervous system. In the word "symptoms" he included those signs of disturbed function which were to be obtained only by the observer.

It had been pointed out by Head and others that every disease of the central nervous system manifested itself by disturbance of function, hence the absurdity of trying to classify such diseases as entirely either organic or functional. The observer was inevitably thrown back upon the disturbance of function as the basis of investigation. The first question which arose was as to the function or functions which were disturbed, and consequently the first endeavour must be to determine the physiological basis and anatomical location of the disturbance. He took as an example a

patient who had a useless arm; in such a case inquiry must be directed to determining at what level of the motor pathway between the cerebral cortex and the muscles the damage lay. Having established the physiological, and if possible the exact anatomical, diagnosis, the question of the pathological cause had to be settled.

The statement was sometimes made that one physical sign was worth many symptoms. While this might be true in many cases, exception should fairly be made in disease of the central nervous system, where it was sometimes possible to make a shrewd guess at the nature of the disease by a careful examination of the subjective symptoms described by the patient. Careful inquiry into the details of many subjective symptoms would provide a useful clue in the diagnosis. Students should be encouraged to inquire into their case histories. In many cases a diagnosis could be made on the history alone. The subjective symptoms of the patient were of great diagnostic value in many diseases of the central nervous system, of which disseminated sclerosis was but one example. It was hardly necessary to emphasize the importance of a complete physical examination of the case. Mistakes were more frequently made from inadequate examination than from any other single cause. The examination should not be confined to the nervous system but include other systems.

The Significance of Pain.

Pain, a symptom common to many diseases of the central nervous system, should be regarded as an exaggerated response by an irritated nerve. The grey and white matter of the central nervous system was insensitive to the ordinary forms of stimuli, and pain in this connexion was produced chiefly either by disease of the meninges of the brain or spinal cord, or by some pathological process which could compress or stretch them, or some lesion which directly related to the sensory afferent neurons in their course outside the spinal cord or brain and within the dural sheath, such lesion being usually of meningeal origin.

Increase of tension was a common cause of pain. Among the characteristic features of pain in increased intracranial tension, the first, generally speaking, was its paroxysmal character, the paroxysms being excited by any sudden form of exertion or change of posture. Mental activity would not uncommonly precipitate a paroxysm of pain. Even when the pain was constant paroxysms of intense pain occurred. The position of the pain was variable. At first it might have a more or less close relation to the lesion which caused it, but more frequently such localization was lacking. The frontal and occipital regions were the parts of the head where the pain was most commonly felt. It did not generally have the throbbing character which was found, for instance, in arterial hypertension, and generally it was relieved by rest in the recumbent position and sometimes by lumbar puncture.

He dealt next with pain in the face due to intracranial tumours. He had seen two cases of pituitary tumour where the distinction between pain in the head and pain in the face was absolutely definite and perfectly well appreciated and described by the patient. Other characteristic forms of pain were those found in lesions in the posterior nerve roots, in cases of syphilis of the central nervous system, and especially in tabes dorsalis. In making an early diagnosis the exact character of the pain assumed great importance. Farquhar Buzzard had given a good description of the "lightning" pains in tabes dorsalis. The pain of tabes dorsalis or of syphilitic disease of the central nervous system did not as a rule radiate in the long axis of the body or follow the course of the nerve distribution. The pain was typically described as stabbing or cutting, and the sensation, as Buzzard said, was as if some sharp instrument were forced into the skin at a right angle to the long axis of the limb. Further, the actual area in which any one pain was felt was usually circumscribed. The lecturer also touched upon pain of central origin, and repeated Gordon Holmes's description of pain of central origin apparently arising from disease of the cervical part of the spinal cord, and also in disease of the posterior lateral part of the optic thalamus.

It had been his endeavour to show how a study of the character and distribution of the pain in disease of the central nervous system could help to localize the site of the lesion and also to elucidate the nature of the disease present. Obviously in this matter it was necessary to depend largely on the co-operation of the patient, which was sometimes difficult to obtain, especially if pain had existed for a long time. The longer the pain was experienced the wider became

its distribution and the feeblor the patient's resistance. Even the most stolid and heroic person could not prevent the tendency whereby repeated attacks of pain or continuous pain produced this inevitable result. Hence the need to go back to the early symptoms which were unclouded by the process of auto-suggestion.

Other Subjective Symptoms.

While pain was the most urgent and most frequent subjective symptom for which advice was sought, there were others which had an importance not always adequately realized. To such subjective symptoms the useful but ugly term "paraesthesia" was generally applied. These abnormal sensations formed an important part in the symptomatology of many diseases of the central nervous system. Such symptoms might be called functional, but it was important not to be led, in the absence of other and more definite reasons, into confusing this diagnosis with one of hysteria. Increasing experience would render it possible to restrict more and more the number of cases in which the observer would be content with such a diagnosis. He did not need to speak of the facility with which subjective sensations, such as numbness and tingling, were ascribed, often correctly, to neuritis, whether peripheral neuritis or multiple neuritis of toxic origin. When it was remembered how lesions of the central nervous system itself could be responsible for severe pains it was all the more necessary to envisage the possibility of central origin for these other subjective symptoms. There were two diseases in which these symptoms were very important—namely, disseminated sclerosis and subacute combined degeneration of the spinal cord. He would emphasize the early occurrence of these purely subjective disturbances. There were, of course, many other conditions in which abnormal subjective symptoms formed the earliest indications of the disease, notably syphilis of the central nervous system.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

SLIPPING RIB.

In view of the interesting article by Mr. R. Davies-Colley on slipping rib (March 18th, p. 432) the following case, which I had noted as "recurrent dislocation with arthritis of costo-sternal joint," may prove of interest.

A Canadian soldier, a man of very good physique, came under my care in June, 1918. He complained that strong forward displacement of the right shoulder was frequently accompanied by pain alongside the sternum, and said that he believed the inner end of the rib slipped out of place. Physical examination demonstrated this beyond doubt; in addition to the dislocation, there were swelling and persistent tenderness, the joint in question being the third right chondro-sternal.

Resection seemed to me to be preferable to a fixation operation, particularly in view of a probable arthritis. The patient agreed, and three-quarters of an inch of the cartilage was resected under local anaesthesia. Villous fringes were found projecting into the joint. When seen nine months later the patient expressed himself quite cured; he was able to "get his full chest expansion again"—it had been prevented by the nagging pain he always experienced at the site of dislocation.

There is no statement in my notes as to preceding injury; it is difficult to be sure after this lapse of time, but my impression is that no such history was given. I personally have been subject to slipping forward of the ninth left cartilage on acute flexion of the trunk on three occasions and am positive the condition cannot be traced to a trauma in my case.

C. JENNINGS MARSHALL.

London, W.1.

I READ Mr. Davies-Colley's article on slipping rib with interest (p. 432), for it bore out precisely my own experience of these cases, of which I have seen several. They have all been in females, and I have failed to find any convenient reference to the condition, though I am sure that I had read of it somewhere and was thus able to recognize the lesion. The patients have, two of them, been unusually thin, with

very flexible lower ribs, but not all of them were delicate women. One case interested me, because removal of the spleen had been advised. In this case the lesion had been originally produced by the patient, when in an almost squatting position, lifting a heavy box with both hands from the ground. The pain was instant and agonizing and a tumour was felt due to the hyperposition of the lower over the upper rib. For some days tenderness remained over the site of the injury. My three cases have all been left-sided. I have found that if the patient can lie quite flat on her back, take her courage in both hands, and take a deep breath, the rib slips back. Abdominal massage to the muscles, and feeding up the over-slim ones, produced improvement; but the stronger patient I have not heard of again, for she left for abroad much relieved at keeping her spleen.

London, W.1.

F. JOHN POYNTON, M.D., F.R.C.P.

The following case may be of interest in connexion with Mr. Davies-Colley's note on slipping rib:

Miss A. B., aged 30, worked in a munition factory during 1917 and 1918. It was customary there to carry shells with the weight supported by the left side. Since demobilization she had complained of pain in her left hypochondrium. The pain was constant, but varied in intensity; it was relieved by rest in bed, but never failed to reappear after exertion. In addition there was much constipation and frequent attacks of colitis.

As enteroptosis seemed marked a belt was ordered; this relieved the symptoms of ptosis, but the pain persisted. Being anxious to eliminate any bowel trouble before investigating the costal cartilages, I sent her to Dr. F. A. Roper of Exeter for his opinion and for an x-ray examination. He confirmed the enteroptosis, but could find no evidence of stricture. Moreover, he was much impressed with the definite localization of the pain to the tip of the eleventh rib. Resection of the end of this rib was done early in February, and has apparently removed the pain.

Although occurring in a floating rib, the condition seems analogous to Mr. Davies-Colley's cases.

Hfracombe.

H. K. V. SOLTAN.

PRIMARY COLECTOMY FOR ACUTE INTESTINAL OBSTRUCTION IN A PATIENT AGED 70.

M. F., a lady aged 70, had been suffering from constipation, with severe colicky pains and vomiting, since September, 1921. In February, 1922, she commenced to vomit, the vomit ultimately becoming faeculent. She was removed to a nursing home, and the condition subsided, but a week later acute intestinal obstruction supervened. The caecum could be felt to be greatly enlarged, but nothing more was found on examination. The abdomen was opened; the caecum was enormously distended; it could be easily lifted out of the abdomen, but midway to the hepatic flexure the mesentery was shorter, so that a certain amount of volvulus was produced. At the splenic flexure was a marked constriction due to malignant growth, the distal end of the colon being contracted to the size of the small bowel. Resection of the growth was decided upon; 8 in. of the colon were removed, and end-to-end union established by two rows of linen thread sutures; difficulty was experienced owing to the great difference in the size of the two ends; no glands were felt in the omentum, and the abdomen was sewn up without drainage.

She passed liquid faeces immediately after the operation, and subsequently made an uninterrupted recovery, leaving the nursing home in twenty-four days after the operation. The growth had so obstructed the bowel by contraction that it only allowed a probe to pass through.

I am indebted to Dr. Bruce, who saw the case in consultation, and to my partner, Dr. T. Murray Newton, for his skilful help.

C. L. GRANTVILLE CHAPMAN, F.R.C.S. (Lond.),
Surgeon, Grimsby and District Hospital.

IN New York 145,000 children have received preventive treatment against diphtheria. Coincident with this effort to confer immunity it has been shown that there is an actual decrease in the number of cases and of deaths in diphtheria. The latter six months of 1921, as compared with the same period in 1920, show a reduction of the number of cases of diphtheria by 1,852, and of the number of deaths by 155.

British Medical Association.

CLINICAL AND SCIENTIFIC PROCEEDINGS.

METROPOLITAN COUNTIES BRANCH: HAMPSTEAD
DIVISION.

A CLINICAL meeting was held at the Hampstead General Hospital on March 9th, when Dr. ANDREWS showed (1) a case of syringomyelia in a girl aged 20, and (2) a case of cutaneous angioma of the neck, which was being treated with trichloroacetic acid. Dr. GEORGE showed a case of enlarged cervical glands of some years' standing, probably due to chronic tuberculosis. Mr. CLIFFORD MORSON showed a specimen of horseshoe kidney, in which the connecting band consisted of renal tissue and contained an accessory calyx. Pyelograms of the case were also shown. Mr. SIMON BORD showed: (1) A case of congenital spastic paraplegia in a boy aged 6, in which laminectomy and posterior rhizotomy had been performed last June. Prior to the operation the boy had never walked. He now walked and ran without support, and his mental condition had markedly improved. (2) A case of dislocation of the shoulder-joint, with separation of the upper epiphysis of the humerus, in a girl, aged 16, treated by open operation. Full movement had been restored to the shoulder-joint. (3) A case of pseudo-coxalgia. (4) Specimens of diverticulitis of the colon removed by operation and of complete rupture of the kidney, also removed by operation. (5) Skiagrams showing positive evidence of a gastric ulcer in two cases. The findings at operation corresponded exactly with the x-ray appearances.

Reports of Societies.

THE AFTER-RESULTS OF COLECTOMY.

In the Subsection of Proctology of the Royal Society of Medicine on March 22nd a discussion took place on the after-results of colectomy performed for colon stasis. Sir C. G. GORDON-WATSON presided.

SIR BERKELEY MOYNIHAN was announced to open the discussion, but illness prevented him from attending. He sent a list of his cases of partial colectomy, including all those operated on up to the end of 1920, numbering 60 cases of primary colectomy and 8 of ileo-sigmoidostomy. Two colectomy cases died as the result of operation, and of the remaining 66 cases replies were received as to 43 (37 of colectomy and 6 of ileo-sigmoidostomy). Among the 37 cases the results were described by the patients or their doctors as "good," "very good," or "excellent" in 15. In all of these there was a gain in weight, no indigestion, flatulence, or discomfort, normal action of the bowels, and full capacity for work and enjoyment. These were all cases in which there had been gross mechanical difficulties, the caecum full, blue, soggy, dependent, and obstructed. Not all patients who had had this condition improved, but all who improved had had this condition. In 16 other cases the result was fair, better general health, but occasional discomfort, in some cases diarrhoea and in others constipation as badly as before, and no substantial gain in weight in any. In 6 cases the results were poor or bad, the patients remaining ill, weak, and miserable. Of the 6 cases of ileo-sigmoidostomy the result was good in two, fair in one, almost unimproved in one, and poor in two. In one of these last complete colectomy was afterwards performed, and though the early result of the operation was good, the patient was no better than before her first operation. In 17 of the colectomy cases and 5 of the ileo-sigmoidostomy cases the appendix had previously been removed without benefit, and 7 of this first category and 2 of the second improved as a result of the later operation. In 20 of the total cases there were constricting bands across the colon, just below the hepatic flexure; in 18 there was common mesentery to the ileum and ascending colon, with very loose and mobile caecum and colon, and in 14 there were adhesions round the caecum, appendix, and ileum.

Mr. E. R. FLINT of Leeds further described Sir Berkeley Moynihan's methods. Sir Berkeley Moynihan rarely practised complete colectomy; he held that the main seat of the disease was on the right side. Stasis was regarded in his

clinic not as a disease in itself but as part of a nutritional disorder, probably arising from deficient or ill-balanced diet; the effect of which was felt by the colon. His successful cases were those suffering from mechanical interference, with thick, soggy colon and constricting bands. Stasis of this type could usually be differentiated from that seen in loose colon before operation. When this soggy type was present it might be expected that hemicolectomy would yield a good result, or, at the worst, that the patient would consider the operation had been worth while. When this type was not present he did not now perform colectomy. The mortality of hemicolectomy was about 25 per cent. If total colectomy gave good results they were no better than with hemicolectomy; while the unsuccessful results were worse than those after the partial operation.

SIR ARTHUR KEITH said that he was a little disappointed with the way in which the statistics had been presented. He protested against results being described as "good," "fair," or "bad," for these terms meant nothing. What should be stated was the extent to which a man who had had a colectomy performed upon him was able to do his accustomed work. Twenty years ago, after Metchnikoff's teaching had gone abroad, the view was widely held that the big bowel was an anomaly, and that the human body would be better without the colon. If that were the case there could be no question about the good results that would follow the removal of the colon. The speaker believed, however, that a good working colon was of great advantage to the human body. The problem now under discussion was whether a man was better without a diseased colon than with it. He had had the opportunity of examining colons excised by Sir Berkeley Moynihan and other surgeons, and he could affirm that in a very considerable percentage of cases the disease was so severe that there could have been no recovery of a normal bowel, but only a bowel in a fibrosed condition, and that being the case he would prefer to be without such a colon than with it. The more he worked at the bowel, small and large, the more impressed he became with the fact that the really important coat was neither the mucous nor the muscular, but the submucosa, which was a great laboratory wherein the food absorbed was turned into a condition fit to pass into the blood. Out of 15 colons excised by Sir Berkeley Moynihan which he had seen, 10 or 11 were of the soggy type in which the muscle coats were inflamed, and it was a problem which he would not attempt to answer as to what would have happened to the patient had such a colon, which was both paralytic and inflammatory, not been excised. There was no doubt that the alimentary canal from end to end had a greater capacity for repair than any other structure in the body; he knew of nothing else with such a plastic and spontaneous power of bringing about union. Another group of cases, distinct from soggy colon, was one of which he had had few examples from Sir Berkeley Moynihan, but many from other surgeons, and which showed pigment-cell changes. The problem here was with regard to the enormous pigmented cells. Not much information was available with regard to this condition, although experimental methods were now being applied to its elucidation, and some valuable work had been done on these lines by McCarrison. Another question of interest arising out of this discussion was the modification of the small bowel after colectomy. He had seen a case in which, ten years previously, the large intestine had been short-circuited, the small intestine opening into the sigmoid. He found that the large bowel had not been entirely thrown out of function by short-circuiting: it did not function in the ordinary way, of course, but it was evidently impossible to keep the large bowel from making the attempt to do its work. The most remarkable thing, however, was the marvellous changes which had taken place in the small bowel. Externally it had become like the large bowel. Its diameter was twice the normal, its coat twice the thickness, and its length one-third of what it was originally. The average length of the small bowel was 22½ feet; in this individual, who had had the large bowel short-circuited, it was 7½ feet. Finally, he wished to know what happened in cases of colitis or intestinal stasis which the surgeon refused to treat.

Dr. A. F. HURST said that the fact that intestinal stasis should be regarded as a subject for discussion in a section of surgery was something of a disgrace to medicine. He believed that colectomy was rarely, if ever, indicated for intestinal stasis in the absence of signs of gross organic disease. Certain statistics from Goy's Hospital showed that although 31

colectomies were performed from 1904 to 1908, and 50 from 1909 to 1913, the operation since then had become increasingly rare; only one such operation was done in 1920, and none at all in 1921. From these statistics the mortality of the operation appeared to be 16.5 per cent. He had never known a patient die from intestinal stasis, and therefore he thought it never could be justifiable to recommend complete colectomy, which had a mortality of somewhere between 8 and 33 per cent., even in the most experienced hands. He had often been appalled to see how light-heartedly colectomy was recommended. It appeared to be forgotten that medical treatment, including baths, dieting, and intestinal lavage, had its place in intestinal stasis. In some cases where colectomy was performed on patients suffering from such conditions as Raynaud's disease quite extraordinary immediate improvement was brought about, but there was an ultimate return to the old condition. He believed that this was due to the bacterial activity normally present in the colon and ascending colon spreading, after removal, into the ileum, which became practically a new colon, so that in a short time the old symptoms returned. The majority of cases of intestinal stasis which were treated with sufficient perseverance by non-surgical measures got well, and even in the small number in which no improvement followed medical treatment the high mortality of operation and the uncertainty of relief made it doubtful whether this operation should ever be resorted to in the absence of gross organic disease.

Dr. VICTOR PARCNET of Paris sent a communication in which, after describing total colectomy as "Arbuthnot Lane's operation," he said that if therapeutic progress was to be made it was not sufficient for experienced surgeons to point to splendid results achieved, but they must draw attention also to possible accidents and explain their causes in detail. Total colectomy was still a very serious operation, and its results were not uniform. He had himself performed 122 operations of short-circuiting, with 8 deaths; 52 total colectomies, with 6 deaths (4 due to parting of the suture and 2 to heart failure); and 22 right-sided colectomies, with one death. Of the total colectomies 20 were performed in two stages, 17 following short-circuiting and 3 following right-sided colectomy. He had never had a fatal result with the two-stage operation. It should be possible in future by eliminating avoidable accidents to reduce the mortality of operation to 4 per cent. At present out of 10 colectomies 9 operative successes might be reckoned on, and one death; and of the 9, 3 might be classed as very good results, 3 as average or satisfactory, and 3 as showing little or no improvement. For some months after total colectomy it was important to ensure regular evacuation of the intestinal contents by liquid paraffin.

Sir W. ARBUTHNOT LANE declared himself in entire agreement with Dr. Hurst that colectomy was due to the hopeless ignorance and incompetence of the physician, and he was glad that Dr. Hurst had recognized it. Colectomy should have no place in surgery. Colonel McCarrison's name had been mentioned that evening. Colonel McCarrison had served for nine years in the Himalayas. During that time he had done over 400 capital operations every year, and he had never seen one case of dyspepsia, one of ulcer of the duodenum, one of appendicitis, one of colitis, or one of cancer. He would like the physicians to think that over. There was no such thing as cancer in uncivilized communities, apart from the consequence of such surface irritations as the scraping of the head by the Chinaman. He wished to state emphatically that he had never laid himself out to obtain favourable statistics at the expense of the patient's interests. If he had tried to interest the medical profession in the beneficial results of operation by publishing records showing a large proportion of success with a minimum of mortality he would have confined colectomy to those cases which were commonly called good surgical risks, but such a course would have been fatal to his object. He had taken no chances. He had been careful not to be held blameworthy in this matter. They all knew that the cases calling for such a radical procedure as colectomy were usually very ill. The cases had been treated medically for a long period, frequently operated on for various end-results, and in a considerable proportion of cases there were other diseases complicating stasis. One case in which he had been called upon to operate was that of a Canadian soldier, seen by forty surgeons in Toronto who would not operate on him, told at the Mayo Brothers' clinic that Lane of England was the only man who could cure him, and sent over to London, accompanied by an escort, as a result of a fund raised on his behalf in

Canada to pay the man's expenses and the surgeon's fee (which latter he did not accept). The man was operated on, returned to Canada well, accompanied by his escort, and was now doing work in the backwoods. It was all very well to tell him that people who were left alone did not die. Sometimes they died by their own hand. One lady came into his consulting room with a revolver, and said, "Are you going to take out my colon, or am I to blow out my brains?" He took out her colon. The risk of this operation varied inversely with the intra-abdominal tension. With a flaccid abdomen in an aged female the risk in colectomy was non-existent. The only great risk arose from adhesions. He was certain that when surgeons realized the immense benefit the patient derived from the operation colectomy would be resorted to more frequently and with greater safety than at present. Dr. Hurst had given the meeting the idea that the operation was obsolete. He himself was doing more colectomies now than he had ever done in his life. Some speakers did not seem to understand what chronic intestinal stasis was. In conclusion, he complained that since he began to do this operation he had received nothing but abuse, not direct, but indirect. Patients came and told him that a doctor had said, "For goodness' sake, don't go to Lane. Whatever is wrong with you, even if it is only a sore throat, he will take out your colon." Another doctor had said, "Don't call Lane in; he will kill you for a certainty." He wished that those whose temperaments led them to take different views from his own would substitute argument for abuse.

Mr. J. P. LOCKHART-MUMFERY said that he had never been one of those who regarded the normal colon as a useless vestigial structure. A colon must have many functions which they did not seem to know much about. He had been struck with the fact that patients who had had a colectomy performed upon them were very subject to poisoning; certainly such people should be careful what drugs they took. There was no doubt that patients could survive a colectomy and become normal members of society, with certain inconveniences such as fluid stools. He had seen one case of intestinal stasis die without operation—a shocking case of auto-intoxication. He thought that colectomy should be done, but only in selected cases—namely, those in which the colon was completely degenerated. He agreed that when medicine came into its own colectomy would not be required.

Mr. E. G. SLESINGER produced statistics relating to 50 cases of colectomy in female patients performed in 1911-12 and their after-history. He had lost the records of the male cases, but his impression was that the results were about the same, save that the mortality was higher. The mortality figures, of course, depended upon the operability figures, and by choosing cases it was easy to show a low mortality. All these 50 cases, however, were those of chronic invalids, their invalidism having lasted for years before operation, and a considerable number were extreme surgical risks. Out of these 50 patients, 2 died from operation, and one other died some months after operation from acute intestinal obstruction. Of the remaining 47 he could only trace 25, but he had every reason to believe that in the 22 untraced cases the results were at least as favourable as in the others. Eighteen of these 25 patients were perfectly well; 3 were definitely better, though still suffering in certain respects; 2 were no better, and 2 had died during recent years, both of them from acute intestinal obstruction. He considered that the results amply vindicated colectomy.

Other speakers in the discussion, who had to compress their remarks owing to shortness of time, included Mr. TYRELL GRAY, who argued that atrophic changes accounted for some of the symptoms which occurred after hemicolectomy, and described the manner in which venous stasis of the bowel occurred in visceroptosis where the normal supports of the intestine had failed, and the mesentery was called upon to support the large bowel, resulting in difficulty of venous return. If colectomy was done after this, it was important to remember that the original cause had not been tackled, and moreover that a piece of bowel had been removed. Dr. L. GROSS gave an account of some experiments in which rats had been fed on vitamin-deficient diet, the results suggesting that vitamin deficiency might be quite important in a number of colonic and ileal stasis cases.

Sir CHARLES GORDON-WATSON, from the chair, said that the Subsection might congratulate itself on the success of the discussion. It had not succeeded in reaching the solution of the entire problem, but it had gone a considerable distance towards it.

ANAESTHESIA IN INTRACRANIAL SURGERY.

At a meeting, on March 3rd, of the Section of Anaesthetics of the Royal Society of Medicine, with Dr. H. J. SHILLER, C.M.G., President, in the chair, Dr. Z. MENNELL read a paper on anaesthesia in intracranial surgery. After referring to the effect of changes in intracranial pressure which come about quickly or suddenly Dr. Menzell briefly depicted the methods of anaesthesia in cranial surgery during the last twenty years at the National Hospital, Queen Square. The danger of chloroform, which was at the beginning of that time commonly employed, was explained by the much higher percentage necessary in the blood for anaesthesia when the intracranial pressure was raised. Directly the tension was relieved an enormous increase took place in the volume of blood flowing through the brain. A dangerous or even lethal dose might suddenly bathe the medullary centres. Anaesthesia deepened directly the dura was opened, whatever anaesthetic was being used. Ether was subsequently substituted for chloroform in the Vernon Harcourt inhaler, and later still it was given from a Junker bottle attached to an oxygen cylinder. Mechanical difficulties led to the substitution of infusion anaesthesia for these inhalation methods. The technique was tiresome and the method expensive. However, hedonal gave good results till the war rendered it unobtainable. Dr. Menzell drew attention to the deceptive rise of blood pressure due to the constant supply of fluid with infusion methods of anaesthesia. From these methods he passed to intratracheal ether, which he now considered the best method for all cerebellar, pituitary, or high spinal operations. The extreme flexion of the neck required for some of these operations can be permitted with no other method of anaesthesia. No sudden fall of blood pressure occurred if haemorrhage was properly controlled. The surgeon can operate without haste and the most formidable cerebral operations can be completed at one sitting. Vomiting, which led to protrusion of the brain and venous haemorrhage, can be more certainly avoided than by any other method. With temporal or parietal operations Dr. Menzell frequently gave ether and oxygen by means of a Junker inhaler. The intratracheal method was less necessary in these cases. Any attempt at swallowing was regarded as an indication to increase the strength of the ether vapour. A quickening of the pulse always preceded a fall in blood pressure. Removal of tumours from the cerebellum or lateral recess often caused serious trouble through direct disturbance of the medullary centres. A transitory severe fall in blood pressure commonly occurred. The method employed by Mr. Sargent of removing these tumours by a suction apparatus greatly lessened the danger. The radial pulse might be impalpable for as long as twenty minutes without serious harm resulting. The lighter the anaesthesia could be kept the better. Dr. Menzell next described the manner in which he used chloroform for an anaesthesia to permit the injection of alcohol into the fifth nerve, gave some statistics of his experience with intracranial operations, and demonstrated the apparatus which he employs.

Mr. PERCY SARGENT said that the variations in intracranial pressure were the most important factor during operations for cerebral tumour. The brain was singularly tolerant of changes of pressure provided that they were brought about gradually. The need of close co-operation between surgeon and anaesthetist was perhaps of greater moment in cerebral than in any other class of operation.

Mr. H. E. G. BOYLE stated that he had good results with euphonyne, gas-oxygen-ether in cerebral cases. Dr. W. J. McCARDIE, Mr. C. H. MORRIS, and Mr. I. W. MACILL also took part in the discussion.

EPIDEMIOLOGY OF SUMMER DIARRHOEA.

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine held on March 23rd, with the President, Dr. A. K. CHALMERS, in the chair, Dr. MARTIN W. YOUNG read a paper by Dr. JOHN BROWNLEE and himself on the epidemiology of summer diarrhoea.

The authors in the first place recapitulated the classical researches of Ballard which led to the enunciation of the view that the prevalence of summer diarrhoea was most closely correlated with the movement of the temperature at the depth of four feet, the ascent of the epidemic curve not beginning until the earth temperature registered 56°F. The important work of Peters led to the idea that it was an accumulation of temperature excess which was

responsible, Ballard's measure being an index of such excess. The authors had analysed the weekly mortality returns of London from 1856 to 1921 and found a high correlation between accumulated temperature over 60°F. and the excess of weekly deaths above 100; but it appeared that in a series of years following 1911, when the maximum of the epidemic occurred later in the season, the correlation was slight. When rainfall was considered it was found that the partial correlation between rainfall and mortality from diarrhoea for constant temperature was zero. An analysis of the form of the epidemic curves led to the conclusion that a change of type had occurred. Up to the year 1899 the curves of the annual epidemic were fairly uniform in type, with a maximum as a rule about the thirtieth to the thirty-third week. In 1899 a sudden change occurred, and the maximum of the epidemic was shifted to a later week. In 1900, 1901, 1904, 1905, 1906, and 1911, although the form was similar to that of the years before 1899, the maximum was later. These curves suggested that the disease termed epidemic diarrhoea might be a mixture of two diseases—one predominant before 1899, the second mainly predominant since 1907. To test this point the annual figures were summed and decennial curves constructed. These latter were then analysed, and it was found that the compound curve could be satisfactorily resolved each into two component normal curves. The maxima of the component curves were at the thirty-first and thirty-sixth weeks in the four decades 1860-69, 1870-79, 1880-89, and 1890-99; in 1900-9 the maxima were at the thirty-third and thirty-seventh weeks, and in 1910-19 one component had a maximum at the thirty-seventh week. The importance of the second component increased with time, and by 1910-19 comprised almost the whole of the curve. A similar resolution was effected of the Manchester data from 1870 onwards. The same remark applied to Liverpool, and, making allowance for the roughness of the data, to the records of several foreign cities. The approximate method used was controlled in one series by the method of resolution devised by Professor Karl Pearson. The resolution having been effected, the explanation of the contradictory results of the tests of correlation emerged, because the correlation between accumulated excess of temperature and the deaths belonging to the early component proved to be large and positive, but the correlation of temperature and deaths belonging to the second component was small and negative. Passing to other etiological factors, a study of the relation between mortality and sources of water supplies suggested that the diarrhoea of infants was less closely associated with variations of the quality of the water than was the diarrhoea of adults. With respect to general sanitation, although it might be no more than a coincidence, yet the fact that the first change of type in London was observed in 1899—that is, a few years after the London by-laws devised by Sir Shirley Murphy began to be enforced—was suggestive. The replacement of horse by motor traffic was another change to be had in mind. Finally, the authors examined the relations observed in different cities between the prevalence of diarrhoea and flies, and remarked that the two prevalences were phenomena which, while they might be dependent to some extent for existence on similar conditions, probably largely meteorological, were best explained by the opinion that flies were in great measure responsible for the dissemination of the disease.

Dr. DUFFIELD, in opening the discussion, said he had never doubted that the rôle of flies was that of carriers, and agreed that the replacement of horse by motor traffic was a very important matter. He had also been struck by the occurrence late in the season of cases clinically indistinguishable from "summer" diarrhoea.

Dr. HANSEN attributed very great importance to the effect of the London by-laws in preventing the accumulation of refuse. He also referred to the possible importance of the change in methods of locomotion, but had not found any excessive prevalence of infantile diarrhoea in the neighbourhood of great stables, although there was an excessive prevalence of flies. In his opinion the work of Peters was a first-rate contribution to epidemiology, and the death of the author a grave loss to science.

Sir WILLIAM MACPHERSON asked whether sufficient attention had been given to the effect of measures taken to protect food from flies. His experience had been that epidemic diarrhoea could be controlled by fly-proofing. Dr. BUTLER saw no reason to doubt that Ballard's rule was a thoroughly safe criterion. Zymotic diarrhoea was almost exclusively a disease of hand-fed children, and the instruction of mothers had to

be considered as a factor of reduction. Dr. GREENWOOD congratulated the authors on their success in analysing the curve, and thought their results did not conflict with those of Ballard and Peters, but threw light on the mechanisms at work. Dr. McKAIL thought that the authors' results admitted of a much simpler explanation than that put forward—namely, that modern methods of prophylaxis had delayed the rise of the annual curve. He also doubted whether sufficient attention had been given to decline of the birth rate; most of the curves shown were of absolute figures.

Dr. LANE-CLAYTON said that in Germany the temperature factor was regarded as of great importance. Although hand-fed children were first attacked, there was, in the extensive epidemic of 1911, a serious incidence upon breast-fed children. The German view was that in institutions all children must be regarded as potentially infective. Dust infection must not be forgotten.

Dr. McVAIL wished to know whether any relation between pasteurization of milk and diarrhoeal prevalence could be shown. Ballard had strongly held that diarrhoea was a specific disease, and he (Dr. McVail) suggested that cases occurred analogous with Sydenham's variola without exanthem (see *Obs. Med.*, iii, 2). Dr. BERTON said there was no general pasteurization in London, but there had certainly been much improvement in the cleanliness of the milk. Dr. DUDFIELD mentioned the increased utilization of dried milks. Dr. GOODALL said, referring to Dr. McVail's remarks, that he had once had in his hospital an outbreak of diarrhoea, and there had been simultaneously cases with severe pyrexia, some ending fatally, but no diarrhoea. Pasteurization of the milk had been carried out, and since then he had never had an outbreak. He also knew that many of the large firms did pasteurize their milk.

The PRESIDENT thought that the paper would throw light upon the cumulative effect of temperature. Until recent years the English rates of mortality in infancy had been higher than the Scottish rates. Pasteurization had been very generally adopted by milk vendors in Glasgow for many years.

Dr. YOUNG, in replying, said that neither the date of its maximum nor the form of the curve was consistent with the simple explanation offered by Dr. McKAIL. With regard to the source of infection, it had to be remembered that what was most important was what happened to the milk after it had reached the home of the consumer.

ALBUMINURIA IN PREGNANCY.

At the meeting of the Harveian Society of London on March 23rd, Sir WILLIAM WILCOX presiding, a discussion took place on albuminuria in pregnancy.

Mr. ALEX W. BOURNE said that the chief line of attack in pregnancy toxæmias was that of chemical examination. It was to the chemical pathologist they must appeal for further knowledge of the disturbance of function. Clinically they were still confused by unco-ordinated lesions and symptoms, and not yet sure which were primary and which secondary. Albuminuria in pregnancy was the name for a group of symptoms of which the most characteristic was the presence of albumin in the urine, and no other sign was constant, though the most frequent was raised blood pressure. By observation of the predominant symptoms it was possible to group patients. The first and commonest clinical type was the renal, in which the condition resembled a subacute nephritis. The second commonest was the cerebral type, a condition in which a series of fits occurred in labour, with few or no warning symptoms except the albumin in the urine (one case of which he had notes had 53 fits after labour, without any premonitory symptoms). The third was the gastric type, characterized by uncontrolled vomiting, and was occasionally met with in early pregnancy, though his experience of it was chiefly in the later months; there was evidence that this chiefly in the later months; there was evidence that this gastric type was really of hepatic origin. The fourth type was the hepatic condition, fortunately rare, though a certain amount of hepatic inefficiency probably existed in all cases of toxic albuminuria in pregnancy. The fifth type was of the uterine type, associated with necrosis of the uterine wall, and consequently serious hæmorrhage. In addition to the albuminuria, frequently there were other toxic symptoms. The incidence of albuminuria in pregnancy was much greater than was commonly supposed. Of some 14,000 cases of pregnancy and labour which he had looked through, 30 per cent. had some degree of albumin.

More albuminuria without high blood pressure, vomiting, or other symptoms was not very important. The occurrence of fits was the most serious sign. The pregnancy was seriously prejudiced from the time of the first fit, and the high rate of incidence of fits in albuminuria—some 46 per cent.—rendered its recognition and active treatment a matter of considerable importance. There were three possible disasters, the most frequent being the danger of onset of convulsions; the second, the complete suppression of urine, due to necrosis of the cortex of the kidney; and the third, jaundice, which was very rare (he had seen only three cases in about fifteen years at Queen Charlotte's Hospital). The number of fits had no relation to the mortality. Some women had a great number and got better, others might have one fit and die. Under some circumstances vomiting might be the most dangerous condition in late pregnancy. Two serious signs of impending trouble in toxic albuminuria were (1) the development of a fresh symptom grafted upon those previously existing while the case was undergoing medical treatment, and (2) a sudden increase in intensity in the symptoms already present.

Dr. EARDLEY HOLLAND said that his colleagues at the London Hospital and the City of London Maternity Hospital were making an investigation of the after-results of all cases of eclampsia and toxic albuminuria of pregnancy which had occurred in the obstetrical wards during the last ten years. The cases of eclampsia alone numbered nearly 250. It was proposed to ascertain, whatever might be the immediate recovery of the patient, the occurrence of remote effects of the disease and the percentage of patients who got permanent damage. They could all recall cases which had suffered chronic renal disease as a consequence of eclampsia. These investigations had not proceeded far, but so far as they had gone it appeared that a fairly high percentage of cases of eclampsia and severe toxæmias of pregnancy showed signs of chronic renal disease or renal inefficiency. Of course, it had to be remembered that patients who had continued ill after their attack of eclampsia were more likely to have remained in touch with the hospital than others who had quite recovered. The question of permanent kidney damage following eclampsia had an important bearing upon treatment, for the longer such a pregnancy was allowed to go on the more likely was this permanent damage to occur. It was often regarded as a triumph if the eclampsia cleared up and the pregnancy went on, but he doubted very much whether it was a triumph. He had seen eight cases in which the fits had cleared up and the pregnancy had gone on, and in only two of them was the result absolutely satisfactory from the point of view both of the health of the mother and the delivery of a living child. He urged that labour should be induced in such cases.

Dr. MACKENZIE WALLIS dealt with the subject of laboratory tests. In normal pregnancy, particularly after the fourth month, the blood-urea content was nearly always below that of the normal non-pregnant woman, and the same applied to the blood-sugar. The diastase content of the urine, on the other hand, was higher in pregnancy. When they came to estimate the blood changes in the toxæmias of pregnancy they found very little variation from those in normal pregnancy. The most striking point in the toxæmias of pregnancy, so far as the blood was concerned, was the marked increase in the cholesterol content; this was increased enormously, and the highest figures ever recorded for cholesterol content had been found in cases of eclampsia. In the urine much more striking changes were noticed than in the blood, particularly with regard to the diastase content, which was a very valuable method of differential diagnosis. High diastase content of the urine preceded albuminuria. He regarded the estimation of urea in the blood and diastase in the urine as the tests of choice in distinguishing between toxæmia in pregnancy and true nephritis in pregnancy. In nephritis of pregnancy the diastase was invariably low, and the lower it was the more unfavourable the pregnancy.

Dr. S. STUART followed on similar lines to the last speaker, recounting some work on laboratory tests which he had carried out under the direction of Sir William Wilcox at St. Mary's Hospital. He considered that the estimation of the urea was very valuable indeed. Dr. C. M. WILSON thought that very often the induction of labour was left too late. The tendency was to sacrifice the interests of the mother to those of the child, and in doing this very frequently great damage was done to the mother. Dr. R. S. O. DODD said that he would like to know how Mr. Bourne proposed to describe on the death certificate the various distinct conditions to which he had alluded. It was only since 1911 that

albuminuria in pregnancy was set out in the Registrar-General's returns as among the accidents and diseases of pregnancy. Dr. R. G. MURRAY thought that there was some evidence that this condition was less frequent among better-class patients than among patients belonging to a lower economic level.

Sir WILLIAM WILLCOX referred in particular to the interest of Dr. Mackenzie Wallis's contribution, showing how in the laboratory these toxæmias of pregnancy could be differentiated. He had drawn attention to the likelihood that the toxins of the corpus luteum were, if not entirely responsible, to a great extent responsible for this extraordinary toxæmia. In the literature of the subject the corpus luteum had been entirely forgotten, and it was very interesting if this insignificant body—as it appeared to them in their anatomical dissections—was capable of results of such great importance. He thought that toxæmias of pregnancy where albuminuria occurred were nearly similar to the conditions one saw in the forms of toxic jaundice. The toxins produced in pregnancy—no doubt normally in the healthy person neutralized and rendered harmless—caused a certain amount of damage to the kidney. It was not damage of the nature of nephritis, but damage of degeneration. The cells of the kidney were damaged, some recovered and some did not, and during pregnancy the patient perhaps developed severe symptoms which left a portion of the kidney cells necrosed. Each successive pregnancy with such a person was likely to be attended with more serious results than normal. Yet in this toxic albuminuria of pregnancy a patient might recover and apparently enjoy normal health.

Mr. BOURNE, in replying on the discussion, said that more than one speaker had alluded to the danger of allowing these albuminuric patients to go on too long without inducing labour. But before one could do anything intelligently an accurate diagnosis must be made, and in many cases this was only possible by chemical examination.

CARDIFF MEDICAL SOCIETY.

A CLINICAL meeting of the Cardiff Medical Society was held on March 14th, under the chairmanship of the President, Dr. F. BUCKNAM, when Mr. C. DE W. GRAY showed a specimen of cerebral abscess secondary to bronchiectasis. The abscess, which was situated in the right temporo-sphenoidal lobe, was almost the size of a walnut and possessed a wall of granulation tissue at least one-eighth of an inch thick; the right lung showed in the lower lobe several rather large bronchiectatic cavities filled with foetid pus. The patient had been admitted to hospital following an accident, but his symptoms and signs pointed to a cerebral condition, not necessarily connected with the accident; it appeared, in fact, from the thickness of the abscess wall in the brain that the abscess might have been present for at least six weeks and that the relationship of abscess to accident was of the nature of cause and effect. From the pus in the abscess the pneumo-bacillus of Friedländer was isolated in pure culture.

Mr. GEARY GRANT showed a left kidney with wedge-shaped caseating masses in the upper half, removed from a man aged 39 who for eight months had suffered severely from polyuria, dysuria, and extreme diurnal and nocturnal frequency. The cystoscope showed a left ureter resembling a golf hole, with swelling and injection of margins and several small tubercles on the outer and upper side. On one occasion jets of pus were seen to come from this ureter, but subsequently the secretion ceased completely from this kidney. Within three or four weeks of nephrectomy the symptoms of cystitis cleared up.

Professor E. EMERY-ROBERTS and Dr. H. A. HAIG showed specimens from a case of primary pulmonary tuberculosis followed by tuberculous meningitis. Both lungs showed extensive apical involvement by numerous tubercles, some of these already breaking down and forming small cavities; the apices of the left upper and lower lobes were all affected, the right mid-lobe being the only one to escape. The bronchial glands showed no signs of involvement. The brain showed a thick yellowish exudate over the ventral and dorsal aspects of the pons and peduncles, and a few tubercles were found on some of the smaller vessels in the sulci between the convolutions round the Sylvian fissure. The cerebro-spinal fluid removed *post mortem* from the brain showed rather numerous tubercle bacilli, a relative polymorphonuclear increase, and a marked relative lymphocyte increase. A few submiliary tubercles were found in sections of the liver.

Professor E. J. MACLEAN showed a case of a large semi-pedunculated fibroma removed from the right labium majus of a patient six months pregnant. Microscopically it was seen to be almost a pure fibroma, only a very few involuntary muscle fibres being present here and there. Removal had been undertaken in order to obviate the condition causing obstruction at labour.

Professor A. W. SHEEN showed radiographs of three "chip" fractures of the phalanges, two in the fingers and one in the toe, and described the cases. He pointed out that such fractures were usually not detected without the use of x rays, when they could probably be found in many cases of severe sprain or dislocation. The treatment was discussed, immobilization in plaster-of-Paris for the majority of cases of finger injury being recommended if the patient would consent.

Mr. S. ALVIN SMITH showed end-results of bone grafting. (a) Gunshot wounds of both forearms, resulting in a 3-inch gap in each radius, at the junction of the upper three-quarters with the lower quarter. A tibial autogenous graft was used for each arm. The inlay method was used at each end in one arm, and in the other the proximal end was inlaid while the distal end was pegged into the cancellous bone of the expanded lower end of the radius; fixation was by soft iron wire. Radiographs taken two years and two and a half years after operation showed thickening of the graft and formation of new cortex. (b) Ununited fractured lower end of tibia, of eighteen months' duration. Operation for freshening ends and fixation by wire loops failed; but bone grafting by means of a "slide inlay" resulted in firm bony union. (c) He also showed the end-results of tendon transplantation for irremediable musculo-spiral and posterior interosseous nerve lesions in four cases.

Dr. G. I. STRACHAN showed: (a) A case of anencephaly, in which the placenta was adherent to the base of the skull by a thick amniotic adhesion, associated with stunting of the right hand; the effect of amniotic adhesions as a possible cause of this malformation was discussed. (b) A section of the uterus with placenta *in situ* removed *post mortem* from a patient who died, undelivered, of eclampsia. The placenta was extensively occupied by haemorrhages, and bleeding had occurred also between the placenta and uterine wall and had infiltrated, to some extent, the uterine muscle. Clinically, profuse *ante-partum* haemorrhage was noted. The effects of *ante-partum* accidental haemorrhage were referred to, and the relationship between this and placental infarction and albuminuria and toxæmia was discussed.

Other cases and specimens were shown by Mr. H. G. COOK, Dr. J. C. GILCHRIST, Mr. CORNELIUS GRIFFITHS, and Mr. J. W. TUDOR THOMAS.

ARTERIO-VEINUS ANEURYSMS.

A MEETING of the Section of Surgery of the Royal Academy of Medicine in Ireland was held on March 10th. Sir W. L. DE C. WHEELER was in the chair, and showed a case of arterio-venous aneurysm of the subclavian vessels. The man was one of two similar cases under his care in Mercer's Hospital. Both men were wounded in 1918 by a bullet traversing the region of the subclavian artery above the inner third of the clavicle. A diffused thrill could be felt, and there was a loud murmur like the booming of artillery in the distance, widely distributed, but with a point of maximum intensity just above the clavicle. In one man the radial pulse was much smaller than on the opposite side; he also had concomitant injury of the brachial plexus, and was distressed by the intense noise of the murmur when he lay upon the affected side. Sir William Wheeler stated that he recently had three other cases of arterio-venous aneurysm in the limbs. In the first, an officer, there was a communication between the vein and artery in Hunter's canal. The vessels were tied above and below (quadruple ligature). The case was cured and there was no apparent disturbance of circulation. The operation was performed one month after the injury. A child of 8 years presented a similar condition above the middle of the thigh, but in this case there was a large pulsating tumour, and at operation, although both artery and vein had been obviously injured, no communication between the two could be found. Four ligatures were applied as in the previous case, with resultant cure, and no circulatory disturbance. This patient also was operated on one month after injury. A third case showed all the characteristic signs of arterio-venous aneurysm of the posterior tibial vessels. The operation consisted of excision after ligation of the vessels above and below; the result was good. Although a spontaneous cure was rare,

there being only two in a series of 447 cases tabulated by Callender. Sir William Wheeler pointed out that the condition was not incompatible with long life. He did not propose to operate on the two cases of aneurysm at the root of the neck at present under review, unless special indications arose. So far as he could gather from recorded literature, results of operation on arterio-venous aneurysms of the subclavian vessels were very discouraging, and the procedure was attended with great difficulty. The proximal dilatation of the artery, the enlargement of the heart, and the general slowing of the pulse in a number of cases were points of interest. In the neck the veins often did not dilate, as the column of blood pushed aside by the arterial inflow found a ready escape through channels equally large with a negative pressure.

Intrathecal Tumour of the Cervical Spinal Cord.

Mr. W. PEARSON described a case upon which he had operated for this condition. The patient was an unmarried woman of 50, who gave a history of pain in the right side of the neck over a period of four years, punctuated by free intervals. The first free interval lasted for two years. She had been treated in hospital on several occasions for the pain, and there were never any other nerve symptoms save occasional attacks of wry-neck. In February, 1921, examination showed that the pain was strictly confined to the area of distribution of the anterior primary divisions of the second, third, and fourth cervical spinal nerves on the right side, and in the absence of other signs the case was regarded as one of cervico occipital neuralgia. As the posterior primary divisions of the nerves were not involved it seemed probable that a peripheral cause might exist, and consequently a block dissection of the posterior triangle of the neck with high division of the affected nerves was performed. The pain ceased for two months and then recurred. She returned to hospital again in July, and again no other nerve symptoms were present. In August a laminectomy was performed with the intention of dividing the nerve roots. On opening the dura a dark red tumour was seen closely applied to the right side of the cord, displacing the latter to the left. It lay in front of the posterior nerve roots and extended up through the foramen magnum and downwards into the spinal canal. The laminae of the upper six cervical vertebrae were removed without reaching the lower end of the tumour, but the latter was then capable of excision after the third and fourth posterior roots were divided. It subsequently measured 6.5 by 2.5 by 1.5 cm., and the pathological report was that the tumour was a spindle-celled sarcoma. The patient's progress was satisfactory at first, but later on signs of compression, varying much from time to time, made their appearance, and the patient eventually died, more than six weeks after operation. No cause of death could be determined at autopsy, the brain, spinal cord, and meninges appearing normal. The experience in this case suggested: (1) In cases of severe persistent pain of segmental type with negative neurological findings, lumbar puncture may aid diagnosis. In this instance it would most probably have shown that obstruction existed in the subarachnoid space. (2) In such cases exploratory laminectomy should be selected in preference to peripheral neurectomy in the first instance. Particularly remarkable and inexplicable was the fact that no pain was referred to the cutaneous branches from the posterior primary divisions of the affected nerves.

Mr. J. T. McCULLAGH and Mr. M. DOCKRELL showed a number of patients fitted with modern artificial limbs and surgical appliances. The demonstration was illustrated by Mr. McKIE, instructor to the limbless at the Special Surgical Hospital, Blackrock, and by his pupils.

At a meeting of the North of England Ophthalmological Society held on March 10th the following were elected to the committee:—President: Mr. G. H. POOLEY, Sheffield. Vice-president: Mr. THOMSON HENDERSON, Nottingham. Treasurer: Mr. HARRY LEE, Leeds. Secretary: Mr. PERCIVAL J. HAY, Sheffield. Members of Council: Messrs. J. Gray Clegg, Manchester, and A. L. Whitehead, Leeds.

A PATHOLOGICAL meeting of the West London Medico-Chirurgical Society was held at the West London Hospital on March 3rd, with the President, Sir G. LENTHAL CHEATLE, in the chair. A series of interesting pathological specimens were shown by the PRESIDENT, and by Mr. MCADAM ECCLES, Dr. HAROLD SANGUINETTI, Mr. DENHAM PINNOCK, Dr. L. R. SHORE, and others. A discussion followed.

Reviews.

TECHNIQUE OF THE TEAT AND CAPILLARY GLASS TUBE.

SIR ALMROTH WRIGHT and Dr. COLEBROOK could not have chosen for their book, *The Technique of the Teat and Capillary Glass Tube*, a more appropriate motto than the famous words of Carl Ludwig, "Dio Methodo ist Alles," for this volume is devoted to an exact description of laboratory methods in which glass pipettes can be employed, with only so much of theoretical consideration as will enforce the argument of the importance of technique.

This, however, appears not to have been the only purpose which the authors had in view in compiling this handbook for the medical research laboratory, for in the preface they seem inspired with missionary enthusiasm to the "general body of the medical profession," whom they wish to convert to the view that "clinical experience . . . unaided by apparatus and technique is for the purpose of research of infinitely little account." By this they mean that in judging, for example, of the efficacy of a remedy by experience alone there are so many fallacies in the selection of the material, in the administration of the remedy, and in the interpretation of results, that such investigations rarely lead to trustworthy generalizations. Mere statistical inquiry also receives from the authors an equally emphatic rebuke, on the ground that it is notably inaccurate. It is maintained, on the other hand, that the researches which can be carried out in a laboratory on the blood and body fluids will often supply precise information as to the absorption of a certain drug, and may indicate exactly what has been achieved by treatment.

The present volume—the second edition of the much smaller book which appeared in 1912—contains important additions and developments. Chief amongst these is a device for lining pipettes and slides with paraffin, which makes it possible to measure small quantities of fluid with almost mathematical exactness, and prevents the contained fluids from absorbing traces of alkali from the glass. Another modification of pipette technique has been introduced under the somewhat misleading title of "Method of washes and mural implantations," which depends upon the fact that when fluid is drawn up into a pipette of a diameter of half a millimetre and subsequently expelled, about one twenty-fifth of its volume remains behind in the pipette, and it is thus possible to make rapidly a one in twenty-five dilution of a fluid. In a similar way it is possible to leave bacteria attached to the walls of a pipette into which divided volumes of serum are subsequently drawn, and each volume of serum in turn will be inoculated with diminishing numbers of bacteria. Such a procedure is obviously of only rough utility, and though the technique may be of value in determining the bactericidal power of serum (for which purpose it was apparently devised), it is doubtful whether it will be of much value in other directions, and it is, perhaps, hardly worthy of being classed amongst the "refinements and developments of the technique." A simple device is described for fitting a tent on to a pipette which is charged with fluid without disturbing the contents, a procedure which has always presented difficulties. More simplified methods have been introduced for the measurement of the coagulation time of the blood, the antitryptic titre of the serum, and the bactericidal power of the blood, and there are three new chapters embodying research work carried out on infected wounds and dealing with the migrations and functions of the leucocytes, the source and origin of protective substances, and the therapeutics of infected wounds. A broad and practical outlook is given to the technique of the examination of the coagulability, alkalinity, and antitryptic titre of the blood by the addition of appendices to the chapter dealing with the clinical significance of the problems involved.

Such are the developments to be found in the latest edition. For the sake of laboratory workers unfamiliar with the first edition—if such there be—it is only necessary to point out that Sir Almroth Wright's book has always been the primer of pipette workers and the standard work of reference for information regarding the making of simple glass apparatus for use in the laboratory. It contains many ingenious devices for measuring small quantities of fluid, and without attention

1 Technique of the Teat and Capillary Glass Tube. By Sir Almroth Wright and Dr. Leonard Colebrook. London: Constable and Co. 1921. (384 pages; 151 illustrations. 42s.)

to the detail so meticulously described in these pages it is impossible to obtain satisfactory blood films for opsonic work. Full information is given on the question of the opsonic power of the blood and the preparation of vaccines, together with many other original contributions to laboratory studies.

One great merit of all the technique herein described is that it is simple and can be carried out in the "side room" of a hospital ward without the assistance of complicated and expensive apparatus. The book will be of interest, therefore, to all medical men who wish to investigate the scientific problems connected with disease. But to those not trained in laboratory work it is only right to say that though the book contains the truth, and, we hope, nothing but the truth, it does not pretend to enshrine the whole truth. In particular the chapter which is devoted to the Wassermann reaction describes only one method of carrying out this test, and this, though a rapid and ingenious modification, is not looked upon with favour by the majority of bacteriologists, by whom it is regarded as less reliable than the orthodox methods. The same warning is applicable to the agglutination section, for though the methods described for this reaction are useful they are by no means all-sufficient.

The correct view to take with regard to this volume is that therein are recorded the researches of Sir Almroth Wright and his colleagues, and the manifold contributions they have made to scientific methods. No further commendation need be given than this.

GASTRIC SURGERY.

In writing their monograph on the *Surgical Treatment of Non-Malignant Affections of the Stomach*,² Drs. CHARLES GREENE CUMSTON and GEORGES PATRY study the indications for operation, the results obtained, and the conditions determining the choice of an operative procedure. Their conclusions are based, apparently, on a digest of some part of the literature of the past twenty years, little reference being made to their personal experience.

The book commences with a long historical account of the various operations which have been performed for the relief of gastric affections, special attention being devoted to the operation of gastro-enterostomy, to which upwards of thirty pages are given. Most of this is of no more than historical interest, and its value in this respect is much diminished by the absence of a bibliography. Undue prominence is given to the history of the efforts to overcome vomiting, due to a vicious circle, and very little space is devoted to post-operative peptic ulcers—a much more important question at this period of gastric surgery. A good point is made in the reference to adhesions of the efferent loop as a cause of mild degrees of reflux vomiting.

The use of Murphy's button in certain cases of gastro-enterostomy, and a belief, apparently, in the spontaneous closure of gastro-enterostomy openings, without antecedent ulceration, sound strange in British ears. The belief, together with the opinion that the stoma does not function when the pylorus is patent, leads the authors to advocate strongly the combination of pyloric exclusion with gastro-enterostomy. These conclusions appear to us to be based on false premises, as it has been shown by Hartman and others that the stomach does function, although the pylorus be patent, and that, so far from closure of the stoma being specially associated with a patent pylorus, in the great majority of reported cases the pylorus was not permeable. The point is of importance, since many surgeons believe that the combination of exclusion with gastro-enterostomy predisposes to the formation of secondary ulceration.

The conditions requiring surgical treatment are next considered under different headings, by far the chief place being occupied by various types of stenosis and ulcer. The conclusions arrived at are very contentious, and the evidence on which they are based is extremely unconvincing. The authors have a marked preference for indirect methods of treatment, especially for gastro-enterostomy combined with pyloric exclusion. The modern radical methods find little favour, and an exaggerated view is taken of the risk attaching to gastric resection in the case of gastric ulcers. Statistics of the cases reported down to 1911, with a percentage of mortality of 20 per cent., are given as showing the risk of these operations. But these figures are valueless

at the present day, when the mortality of partial gastrectomy for ulcer in the hands of skilled surgeons is very little higher than that of gastro-enterostomy. So obsessed are the authors with the value of the operation of gastro-enterostomy that they regard it as the one most commonly applicable to cases of severe hæmatemesis when operative treatment is decided on. Ptois, nervous dyspepsia, disturbances of secretion, tubercle, syphilis, and traumatic affections are all discussed shortly, but the main bulk of the work is concerned with ulceration and its complications.

PSYCHOLOGY AND THE TEACHER.

Dr. CRICHTON MILLER has written *The New Psychology and the Teacher*³ for those who are in any way interested in the education of the young. He does not profess rigid adherence to any one school, though his views approximate to those developed by Jung, but he is convinced that modern trends in psychology include much of value to the educationist. Analytical psychology, it is suggested, not only throws direct light on the development of the child, but it frees the teacher's own mental and emotional life from bias and repression, and thus gives him that self-knowledge which endows him with a clearer sight and a greater freedom of action in helping the child. The author is opposed to the idea that the teacher should utilize his knowledge by endeavouring to analyse the children he teaches, and he points out that the analysis of the child and adolescent is a procedure of great delicacy. It is perhaps as well that this should be specifically stated, as some writers have advocated the use of the psycho-analytic method by teachers, in spite of the fact that every nervous child necessarily involves definitely medical problems.

In successive chapters the author develops his subject under the following headings: authority and suggestibility; reality and phantasy; the emotional development of the boy and girl; the unconscious motive; mental mechanisms; dream symbolism; the herd instinct and the herd ideal; and educational methods. Each section is preceded by a useful synopsis of its contents, and the various subjects considered are explained clearly and in a manner quite comprehensible to the non-medical readers for whom the book is intended. In some directions Dr. Miller is rather vague in his psychology, as for instance when he refers to the necessity for "the adjustment to the Infinite" in describing the emotional development of a boy. It is also surely rather an extreme statement to make that "it is useless for a person to consider himself an adult while he is still pretending to himself and to the world that he does not know whether there is a God, and is indifferent on the subject." There must be quite a number of thoroughly normal people who have no decided views on subjects of this kind. A question we should like to have seen more fully treated is the age at which a boy should leave home and go to a boarding school, because it is one which gives many parents a good deal of anxiety. Dr. Miller suggests 12 as the most suitable age, but there is of course an increasing tendency to make it much earlier. A famous headmaster is reported to have said: "The more I see of the average parent the more I admire the average boy." If this be a correct estimate of the modern parent perhaps the earlier a boy is sent away from home the better it will be for the development of his character!

COLLECTED PAPERS OF THE MAYO CLINIC.

As the twelfth volume of the *Collected Papers of the Mayo Clinic*⁴ contains 124 articles arranged under ten heads, it is obviously impossible in the available space even to mention their titles. As will be generally expected, the majority of the papers are surgical; but in the section on the ductless glands, which contains eleven articles, the first is on the fundamental classification of disease by the basal metabolic rate; thus, just as the temperature chart divides diseases into two groups, the febrile and the afebrile, so the basal metabolic rate calls into being three categories—namely, diseases with a normal basal metabolism (a normal heat production), those with a decreased and those with an increased rate. For practical purposes an increased basal

³ *The New Psychology and the Teacher*. By H. Crichton Miller, M.A., M.D. Edin. and Paris. London: Jarrolds, Ltd. 1921. (Cr. 8vo, pp. 231. Price 6s. net.)

⁴ *Collected Papers of the Mayo Clinic, Rochester, Minnesota*. Vol. xii. 1922, published September, 1921. Edited by Mrs. M. H. Mellish, Philadelphia and London: W. B. Saunders Co. (Roy. 8vo, pp. xi + 1392; 445 figures. 10s. net.)

² *Surgical Treatment of Non-Malignant Affections of the Stomach*. By C. G. Cumston, M.D., and Georges Patry, M.D. With an Introduction by Sir B. G. A. Meynham, K.C.M.G., C.B., M.S. London: W. Heinemann (Medical Books), Ltd. 1921. (Demy 8vo, pp. x + 342. 15s. net.)

metabolic rate indicates whether due to Graves's disease or to . . . provided active acromegaly is ruled out and the group of febrile diseases eliminated by a normal temperature. Mr. W. M. Boothby follows up this paper with one on thyrotoxic adenoma, in which, as shown by H. S. Plummer in 1913, the hyperthyroidism is quite distinct from that of exophthalmic goitre. The relation of hyperthyroidism to diabetes mellitus is discussed by Professor Reginald Fitz, and the activity of the surgeons is shown by Dr. de Pemberton's analyses of over four thousand thyroidectomies in three and a half years, of which five hundred and forty-two were substernal and twenty-five intrathoracic goitres. Professor E. C. Rosenow's papers on influenza and influenzal pneumonia are well illustrated, and Dr. Stokes has several interesting articles in connexion with various aspects of the salvarsan treatment of syphilis.

Dr. W. J. Mayo contributes no fewer than eight papers dealing with such various subjects as the calloused ulcer on the posterior wall of the stomach, the conservation of the menstrual function, haemolytic jaundice, and the relation of anatomy to present-day surgery; in the course of the last article he has occasion to quote a surgeon of the past to the effect—"Damn the anatomy, stick close to the bone," and therein is contrasted the vigorous language of a bygone day with a most gratifying unfamiliarity with such words and their spelling on the part of one of the famous chiefs of the Mayo foundation. Professor Charles Mayo with five articles, and Professor L. B. Wilson with six papers, set a good example of continued hard work. The volume is generously and successfully illustrated, and cannot but excite sincere admiration and a most cordial welcome.

MEDICAL HISTORY.

THE final number of volume iii of the *Annals of Medical History* has on its cover the portrait of Dr. John Bard, who was educated in Philadelphia under Dr. John Kearsley, senior, and was a successful physician in New York, where his son Samuel founded the first medical school of that city. Reference is made to John Bard in Dr. W. S. Middleton's well-illustrated account of the two John Kearsleys, uncle and nephew, of Philadelphia. In his final instalment of "Montaigne and Medicine" Captain J. S. Taylor, of the United States navy, traces the essayist's travels in search of relief from renal lithiasis, and gives numerous extracts from his essays, including some on death and old age. Dr. Jacob Rosenbloom records the forty years' friendship and many journeys together in Europe, Asia, and Africa of Dr. Thomas Hodgkin and Sir Moses Montefiore (1784-1885), and mentions that, in addition to describing the disease to which Sir Samuel Wilks unselfishly attached his name, Hodgkin anticipated Sir D. Corrigan by three years in his account of aortic regurgitation. Dr. John Ruhlrich's analysis of the literary activities of Dr. John Ferriar of Manchester is mentioned on page 531 of this issue. Mr. C. Sayle, of the University Library, contributes a description of the library of Thomas Lorkyn, Regius Professor of Physic in the University of Cambridge (1564-91), which includes among its 252 volumes eleven incunabula, and is, indeed, his monument, for, unlike his contemporary John Caius, he wrote very little, and travelled not at all. By a happy thought Mr. R. T. Gunther has published for comparison the list of the library ("the rewe of bookes") of Nicholas Gibbard, M.D., sometime demy of Magdalen College, Oxford, and a contemporary of Lorkyn.

Dr. W. J. Turrell, who lives close to Magdalen College, writes attractively on three electrotherapeutists of the eighteenth century—John Wesley, J. P. Marat the revolutionist, and James Graham the fanatical quack, than whom it would be difficult to find more divergent characters and temperaments. Dr. William Abbott's sketch of Dr. Erasmus Darwin (1731-1802) contains a reference to the literary coterie in Lichfield, and to the absence of mutual admiration between Darwin and Dr. Samuel Johnson, with the comment, "probably a case of two lions each thinking the other superfluous on the (Lichfield) shore." Dr. O. C. Gruner writes on "The interpretation of Avicenna," Dr. Jonathan Wright on "The forerunners of Empedocles and the nature philosophers," and Dr. C. Greene Cumston on the history of the treatment of the surgical affections of the lachrymal

apparatus. In a short note on "Emerods, mice and the plague of 1 Samuel, chapter iv," Professor D. Fraser Harris identifies emicruds with the bubonic swellings, and comments on the association of bubonic tumours and rodents at a date so remote from the discovery that rodents are a necessary link in the production of human bubonic plague. The psychological mechanisms and determinants of medical satire are discussed by Dr. Isador H. Coriat of Boston, who remarks that Molière's satire of doctors and medicine was a sort of compensation for his own incurable malady, and was probably connected with the deaths of his son and an intimate friend from the administration of antimony. The editor writes on *Le Caducée*, a play with a miserable charlatan as its central figure, which was produced for the first time in Paris a year ago, and is from the pen of André Pascal (the *nom de plume* of Baron Henri de Rothschild), a member of the medical profession; the play should be seen or read by every medical man, for though the quack has often been portrayed on the stage the realism has never been so vivid and grim. Dr. Cowdry writes attractively on Taoist ideas of human anatomy, derived from a visit to the library of the White Cloud Temple near Peking.

FORENSIC OTOTOLOGY.

THE medico-legal aspects of otology are often of considerable importance in the civil and criminal courts, in workmen's compensation cases, and nowadays in the assessment of pensions and awards for injuries received in the war. The attitude of the War Office towards this speciality is, perhaps the reason why an authoritative work on the subject has not been produced by a British otologist. Books written in foreign countries, where the legal practice is essentially different, are naturally of less value here from this point of view, but the book on forensic otology which Dr. F. Imhofer of Prague has written in German will nevertheless repay a careful perusal, for, apart from the strictly medico-legal aspect, he provides a very thorough and careful description of practically every form of injury which can possibly affect the ear. Special attention is paid to war injuries for most of his experience was obtained while in charge of the aural department of the military hospital at Cracow from 1915 to 1918. The book is intended for the aural specialist, and is too technical to be of use to a lawyer; therefore the first forty pages on anatomy and physiology might well have been omitted. The second chapter is devoted to the examination of the ear from the forensic point of view, and the section on the detection of malingering is particularly interesting; the author does not mention the method of detecting simulated unilateral deafness by speaking through a binaural stethoscope, or similar arrangement of two tubes, one of which is blocked. The third chapter comprises the main part of the book; it deals in great detail with injuries of the ear they are arranged, not in the anatomical order of the part injured, but according to the cause—cuts, blows, firearm sudden variations in air pressure, and so forth. This chapter contains reports of many interesting cases from the author's own experience and from that of others, and there is an interesting section on self-mutilation with intent to avoid military service, which would appear to be somewhat frequent.

The fourth chapter is on malapraxis, among instances which the author gives prominence to unskillful attempts to remove foreign bodies and the syringing of a traumatic rupture of the drum. The final chapter discusses the relationships of aural disease and psychological disturbances, and the book closes with a full bibliography and a good index. It is a monument of careful work and full of interest to the otologist.

ENDOCRINOLOGY.

THE enlarged third edition of Dr. Cobb's book on *The Organs of Internal Secretion* provides general practitioners with a full and up-to-date account of the diseases of these glands, and with a manual of the use of glandular extracts in the treatment of disease and ill health. Dr. Cobb is a firm believer in the general utility of treatment with extracts of the thyroid, pituitary, adrenal, and other glands.

Annals of Medical History, New York, vol. iii, No. 4, December, 1921. (Series No. 12). Edited by Francis B. Packard, M.D. New York: Published quarterly by Paul B. Hoeber. (Mod. 4to, pp. 301-415. Yearly subscription 8 dols., single numbers 2.50 dols.)

Gerichtliche Ohrenheilkunde. Von Dozent Dr. R. Imhofer. Leipzig: Curt Kabitzsch, 1920. (Roy. 8vo, pp. 248; 2 plates and 60 figures. M. 10.)
The Organs of Internal Secretion: Their Diseases and Therapeutic Application. By I. Geikie Cobb, M.D., M.R.C.S. Third edition. London: Baillière, Tindall, and Cox, 1921. (Cr. 8vo, pp. 353. 10s. 6d. net.)

and looks to see an increase in their employment in general need. His pages are full of information, and contain many quotations from other authors who have written so largely about the endocrine glands. It would be a convenience if authors could come to some agreement about the exact form of the adjective "endocrine," which has as common variants in English medical literature the words "endocrinous" and "endocrinic." Dr. Cobb solves the problem by using all three.

NOTES ON BOOKS.

To the constant stream of books of instruction for the expectant mother Dr. R. DOUGLAS HOWAT has contributed yet another, which he entitles *The Threshold of Motherhood*.⁸ It is a pleasantly and simply written little book of fifty pages, beautifully printed on good paper, and unobtrusively but neatly bound. The subject-matter is, of course, the same as in other books of a similar nature—the symptoms and hygiene of pregnancy, the preparations for labour, an outline of the clinical course of labour, and the preparations for the reception of the baby and its management during the first weeks of life. As compared with the transatlantic books of this kind, Dr. Howat's volume does not go into so much detail, and for this it is none the worse. The author keeps to the essentials and deals with them very lucidly and simply, so that no intelligent woman could fail to understand the teaching he inculcates. Furthermore, the book breathes a certain atmosphere of placid confidence and encouragement which should bring comfort to many a young woman looking forward to her first confinement with some not unnatural trepidation. Dr. Howat's book is not only a safe and sound one to put into the hands of any such woman, but it is, in our opinion, superior in several respects to the general run of such volumes.

A new edition of the *Pharmacopoeia of King's College Hospital*⁹ has just been published, sixty-five years after the appearance of the first. In addition to some 85 pages of useful and well-tryed prescriptions the little volume includes valuable notes on the preparation of foods, infant feeding, diet in diabetes, urine and other tests, external therapeutic methods, poisons and their treatment, and a table of doses, etc.

BOOKS FOR MOTHERS.

So many books are written nowadays for the improvement and education of mothers in the art of bringing up their children that one almost wonders that matrimony survives as it does. *See for Parents and Teachers*¹⁰ is a somewhat sentimental work adorned with quotations from the best authors and poets, in which the processes of generation in plants and animals are traced, and subjects like marriage, purity, and eugenics are discussed in a manner devoid of offence. *The Care of the Adolescent Girl*¹¹ deals with the psyche of the budding girl, the sublimation of libido, love, and the future of the adolescent female. This is a rather abstruse and perhaps unpractical volume, conceived on Freudian lines, and suitable only for the emancipated woman. *Woman from Bondage to Freedom*¹² is a stirring blast of dogma, written for the American public, and encouraging women, mothers included, to take their rightful place in the world. *The Prospective Mother*¹³ by Professor SLEMONS, may be recommended to those in search of a sensible and simple book on the subject with which it deals. *The Mental Hygiene of Childhood*¹⁴ by Dr. WHITE, is a book for those who wish to have placed before them their responsibilities as bringers-up of young children. If boys are bad boys, it is the parents that are to blame; and family life is a thing that children can have too much of. Dr. White traces most motives to the sex instinct; his book may be recommended to the discriminating reader.

⁸ *The Threshold of Motherhood: A Handbook for the Pregnant Woman.* By Dr. R. Douglas Howat, LL.B.C.P. and S. Edin., LL.B.P.S.Glasg. Glasgow: The Glasgow Press, 1922. (Pp. 49. Price 3s. 6d. net.)

⁹ *The Pharmacopoeia of King's College Hospital.* Compiled with the assistance of the staff of the hospital. London: C.S. M.P.S. London: Adlard and Son and interleaved, 4s.)

THE OXFORD AND CAMBRIDGE REPORT.

In November, 1919, a Royal Commission was appointed in consequence of applications from Oxford and Cambridge for permanent grants from public money to meet the increased costs resulting from the war. The Commission was instructed to inquire into the financial resources of the universities and their colleges, into the application of these resources, into the government of the universities, and into the relations of the colleges to the universities. Mr. Asquith was chairman of the Commission, which worked in three sections—Oxford, of which he was chairman; Cambridge, of which Mr. Gerald Balfour was chairman; and Estates Management, of which Lord Ernle was chairman. The report, issued at the end of last week, falls into three parts: The first is a general review, the second gives the detailed recommendations of the Commission, the third contains the report of the Estates Management Committee. We may dismiss the last part by saying that the Commissioners recognize that it would be unwise to part with land which may be required for the expansion of universities and colleges, and for the development of schools of agriculture, or land which has any value for building or mineral development.

The general review in the first part of the report contains an historical survey, the most striking feature of which is the enumeration of the advantages the universities of Oxford and Cambridge have derived from possessing residential colleges, the institution of which began as long ago as the thirteenth century.

SCIENTIFIC DEPARTMENTS.

The Commissioners note that a considerable amount of time is still spent in the university laboratories of Oxford and Cambridge on instruction in elementary science which could be given at school; this is rendered necessary by the fact that there are still many schools in which the provision of scientific instruction, and more especially laboratory practice, is insufficient. As elementary teaching must therefore be continued in the universities, the Commissioners consider that there is much to be said for the erection at both universities of light and cheaply built laboratories of one story to serve for elementary instruction in all subjects and for examinations. In this way space would be set free in the present university buildings.

The Commissioners are of opinion that a large proportion of the laboratory fee for ordinary students and the whole fee for research students should be paid into departmental funds. The modern universities have recently raised their fees by from 30 to 50 per cent. without provoking comment or affecting the number or type of students. The conclusion is that there is no reason why ordinary students attending laboratories at Oxford and Cambridge should not pay fees up to £50 a year, and full-time research students a similar sum. Every research student or investigator in a scientific laboratory involves a serious expense to the university, and the cost must, so far as it is not met from fees, fall on the general funds of the university. It is suggested that British universities should adopt a uniform policy with regard to the matter of fees paid by research students, more especially by those coming from foreign universities.

Oxford.

The report states that the original application for parliamentary grants, which led to the appointment of the Royal Commission, was an appeal from the heads of the scientific departments submitted to the Board of Education in March, 1919, asking for an annual grant of about £17,200 in respect of sixteen departments, and for a capital sum of £163,000 to meet the requirements of six of their departments. The annual grant asked for was only intended to provide for the work as it had been carried on before the war, and it was stated that further grants would be required as the departments expanded, and that in all probability a larger proportion of undergraduates would study science in future. The Commissioners recognize that Oxford has for a long time been unable to play her full part in scientific teaching and research, and that though many generous benefactors had been received they were not comparable to the large sums which scientific studies had attracted to many other universities in recent times. The teachers have been too few, and on the whole inadequately paid. In several instances the accommodation is insufficient and the equipment incomplete. The number of students, and particularly of research students, has been in some instances lamentably small, and,

in spite of brilliant exceptions, the output of work less than should be expected. The Commissioners consider that a great opportunity has come for science in Oxford, and note that the Natural Science School has grown rapidly, the number of candidates in the final honours school having risen from 96 in 1914 to 174 in 1921. Although in the seventeenth century Oxford had a brilliant group of scientists, the honours school dates only from 1853, and the real development of the modern science school from the erection of the university museum (1855-60). This has had a marked influence upon the conditions of science teaching and research in the university, and in accordance with the original scheme the scientific departments have grown up around the museum and in close association with it. This system of concentration had many obvious advantages, but owing to the area being restricted difficulties of accommodation have arisen and there is no comprehensive scheme of future development. Still the Commissioners consider concentration so important that they favour a proposal, made by the heads of scientific departments, that a proportion of ground in the University Parks, including the present museum and observatory, and amounting in all to fifteen acres, should be reserved for scientific extensions and developments. The Commissioners consider that more accommodation is urgently required, but hold that the details should be left to the decision of the university. Owing to the difficulty of establishing university laboratories a few colleges built laboratories for specific purposes; they have been of the greatest possible value, but they have now become inadequate both in size and equipment, and it is considered that teaching should be provided in one or more university laboratories.

Cambridge.

The Commissioners state that "during the last century the science schools at Cambridge have acquired a position which it is no exaggeration to say is unique in the history of science. They have been centres of fundamental researches in almost all branches of science, as well as training grounds for teachers who have become eminent in their subject and have filled important appointments in many of the universities of the empire. The activities of these schools show no sign of slackening, and the task before the university is to maintain the present position rather than to introduce reforms, except such as are necessitated by the changing conditions of the time." The Vice-Chancellor informed the Commission that to achieve this and an additional annual sum of not less than £14,300 is required for the scientific departments, excluding medicine, and that £7,000 a year is needed for medicine, including £2,100 for human anatomy. In addition large sums are still needed for building purposes.

Financial Proposals.

The Commission recommends that both universities should have full power to fix professorial stipends. It is considered that the average normal stipends now paid to professors and to other teachers and officers of the university are wholly inadequate, and the Commission recommends that the normal stipend of a whole-time professor (for the year 1921) should be about £1,200 a year, but that the stipends of readers and university lecturers should be fixed in accordance with the needs of the work. It is further recommended that the federated superannuation system of the universities should be applied to both Oxford and Cambridge, and that a special grant should be paid by the University Grants Committee to recognize past services for pension.

The Commissioners find that the available incomes of the universities and the colleges together, including the existing emergency grant (£30,000 paid by the State and certain older State grants for specific purposes) amounted in the year 1920, at Oxford to £824,710, and at Cambridge to £719,554 (excluding certain payments received from undergraduates for service). Though these figures are impressive and show that the universities and colleges have at their disposal a very large revenue, even without the State grants already paid to them, the Commissioners are clearly of opinion that the sums available are totally insufficient to meet the existing needs of the universities and colleges; they therefore recommend:

1. That annual grants be paid by the State to each university as follows:

For general purposes...	£90,000
For the Bodleian Library, Oxford, and the University Library, Cambridge	£10,000
	£100,000

2. That, in addition, a lump sum be paid for pension arrears.
3. That special annual grants, on the following basis, be paid to each university:

For the Women's Property Committee or similar body (for a limited period of 10 years)	£4,000
For the Extra-mural Board	£6,000
	£10,000

OPERATIONS FOR TONSILS AND ADENOIDS.

RECOMMENDATIONS BY THE COUNCIL OF THE SECTION OF LARYNGOLOGY OF THE ROYAL SOCIETY OF MEDICINE.

The Council of the Section of Laryngology of the Royal Society of Medicine has drawn up the following memorandum on the general hygienic conditions which should be observed in performing operations for the removal of tonsils and adenoids. It has forwarded a copy to the Minister of Health, and the memorandum will doubtless also receive careful consideration from the President of the Board of Education.

Memorandum.

In view of the great number of children requiring operations for the removal of tonsils and adenoids, and of the varying standard of the provision made by hospital and local education authorities for such operations, the Council of the Laryngological Section of the Royal Society of Medicine, after careful consideration, desire to make the following suggestions:

1. That all clinics, whether at hospitals or schools, should be in the charge of surgeons with special experience of diseases of the nose, throat and ear, so that, *inter alia*, a wise selection may be made of cases requiring operation, and others not requiring operation may be appropriately treated.
2. That all patients requiring operations for tonsils and adenoids should have in-patient institutional treatment, and that a stay of at least forty-eight hours should be insisted on, and a further stay if thought advisable by the medical officer in charge.
3. That parents should be given printed instructions as regards the preparation of the patient for operation, and of the room to which the patient will return.
4. That before the patient is admitted for operation inquiries should be made by a responsible authority as to the home conditions and circumstances, especially with reference to the presence of infectious disease.
5. That when the patient leaves the hospital printed instructions with regard to after-treatment should be given (as per scheme appended).
6. That anaesthetics should be given by anaesthetists with special experience of these operations.
7. That after the patient leaves the hospital with the printed instructions for after-treatment arrangements should be made for the supervision of a qualified visiting nurse.

The Council were of the opinion that where it is impossible in large cities to provide hospital accommodation for all the cases the provision of open-air buildings near the city, adequately equipped for operative treatment, would offer many advantages. These would be specially useful in connexion with school clinics.

Until such provision of adequately equipped in-patient clinics can be arranged, and where it is not possible to keep every child in hospital for forty-eight hours after operation, and the child is operated on in an out-patient department, the Council recommend that several further conditions should be fulfilled:

1. That printed instructions should be given to the patient with regard to preliminary preparation, and investigation should be made beforehand—for example, by a "care committee" or a visiting nurse—as to the adequacy of the home accommodation and supervision, and also the absence of adverse sanitary conditions, risks of contagion, etc.
2. That proper waiting-room accommodation should be provided for patients before operation.
3. That the recovery room should be scrupulously clean, warm and well ventilated, and provided with separate beds or couches for each patient.
4. That patients should be detained in the recovery room until pronounced fit to leave by the surgeon in charge or his deputy.
5. That the recommendation that the child should be visited by a nurse after discharge from the hospital should be insisted on with even greater force in the case of children who are denied the safeguards of in-patient accommodation.
6. That every child who is sent home on the day of operation should be transferred by an ambulance or hired conveyance. Travelling by public tram, bus, or train so shortly after operation is most undesirable, and a source of distress and often of infection.

(Signed) W. MILLIGAN, President of Section;
WALTER G. HOWARTH, Secretaries of Section;
T. B. LAYTON

March 22nd, 1922.

British Medical Journal.

SATURDAY, APRIL 1st, 1922.

THE ROUTINE OF OPERATIONS FOR TONSILS AND ADENOIDS.

THE question whether the present arrangements for operating upon tonsils and adenoids in out-patient departments of hospitals and clinics, under which the children are commonly sent home soon after recovering from the anaesthetic, constitutes a proper way of dealing with the condition was raised in our columns in November, 1919, by Mr. Douglas Drew, who had the support of Dr. Peter Macdonald. A fresh stimulus was applied in an article by Mr. E. Watson-Williams, published on December 11th, 1920, in which it was pointed out that the morbidity among children operated on in an out-patient department was over four times as great as among the in-patients. Towards the end of 1920 and at the beginning of 1921 many letters were published in this JOURNAL, dealing with the subject from different angles, and to this correspondence most of the leading throat surgeons of this country contributed. The general opinion was that although it might not be reasonable under present financial conditions to expect hospital authorities to provide the necessary accommodation for the ideal treatment of these cases, yet something ought to be done to enable the children to obtain full benefit from the operation while lessening the risk of complications following it. If the choice of the surgeon lay between operating under the present comparatively unsatisfactory conditions, or not operating at all, then the gain to health by performing the operation was thought to be greater, even taking the risks into consideration, than by not performing it.

The problem has been taken up at this point by the Council of the Section of Laryngology of the Royal Society of Medicine; after careful consideration this body, whose right to give an authoritative opinion will be generally recognized, has made a number of suggestions, which are published at p. 526 of this issue. All cases of enlarged tonsils do not, of course, require operative treatment, and the first of the Council's resolutions emphasizes the need for adequate experience in diseases of the ear and throat by the surgeon in charge of the clinic, so that only those cases for which operation alone can suffice should undergo it. Where, however, the enlarged tonsils are actually diseased, and where adenoids are also present, operative treatment is rightly believed to be the only treatment worth considering. In some newspapers it has lately been suggested that operative treatment was unnecessary for tonsils and adenoids, and that some so-called medicinal treatment should suffice. Though much of the criticism was ill-informed, or expressed in exaggerated terms, yet it rested upon a certain substratum of fact, and it is for the medical profession to take steps to remedy defects in administration which can be shown to exist. Several abstracts of papers published in foreign medical periodicals recommending treatment by x rays have recently been published in the *BRITONE*, but no authority in this country has so far suggested that x rays could do more than diminish the size of enlarged, but otherwise healthy, tonsils. In slight cases of adenoids, and when the patient can be placed under good hygienic conditions, iodine in various forms (chiefly certain of the iodides) has been proved to be useful, but its curative value has very definite limitations.

The value of operative treatment for tonsils and adenoids is so widely recognized that the demands have outstripped the resources of the hospitals. The education authorities have done much for the children under their supervision, and in some areas have gone far towards making good the shortage in the voluntary hospital facilities for the treatment of ear and throat diseases; but in many districts even to-day the facilities for the proper treatment of enlarged tonsils and adenoids are lamentably defective, and it must, we fear, be admitted that in some hospitals and clinics the conditions under which the operations have to be performed are far from being in accord with the principles of modern surgery. Although it is clearly impossible to accomplish all that is desirable, since the operations are often urgently required, it is not too much to demand that proper precautions should be observed and proper facilities provided. The Council of the Laryngological Section recommends that in all cases the child should be kept under observation in suitable surroundings for at least forty-eight hours after tonsils and adenoids have been removed, and points out that the period of detention may have to be prolonged should the medical officer in charge consider it advisable. It is suggested that where, in large cities, it is not possible to provide hospital accommodation the provision of an open-air building near the city, adequately equipped for operative treatment, would offer many advantages and would be specially useful in connexion with school clinics. Where all the children operated on cannot be kept in hospital for forty-eight hours much may be done, while waiting for the establishment of adequately equipped in-patient clinics, by a "care committee" or a visiting nurse, who would make preliminary preparations before the operation and visit the patients after they have returned home from the recovery room. The recommendations put forward by the Council of the Section of Laryngology are reasonable and expressed in guarded language. We hope that they will be acted upon by education authorities in consultation with the hospitals. If the former, through their medical officers, take the responsibility, as they do, of advising and insisting upon children being operated upon, and if, as appears to be the case, the courts of law support them in this course of action, every effort should be made to ensure that the operation is rendered as free from risk of complication as possible.

ATMOSPHERIC POLLUTION.

THE Meteorological Office, under the Air Ministry, has issued the seventh report¹ of its Advisory Committee for the Investigation of Atmospheric Pollution. The report deals with observations made in the year ending March 31st, 1921. It contains many tabular statements, various charts, and a large amount of detail relating to the work of that year. It includes also an article by J. R. Ashworth, D.Sc., on a twin atmospheric pollution gauge, and three articles by J. S. Owens, M.D.—on the November fogs in London, dust in expired air, and the relation of visibility to suspended impurity.

The report discusses, in guarded terms, the effect of suspended impurity on health. Statistics of the daily death rate in London for the quarter ending December 31st, 1920, obtained from the Registrar-General, were correlated with the data of atmospheric impurity. The death-rate curve would of course follow, not coincide with, the impurity curve if cause and effect were the relation between them; a diagram given in the report indicates some degree of sequence compatible with that thesis. A complicating factor, however, is pointed out in respect of temperature, which is lowest when

¹ H.M. Stationery Office; through any bookseller. 2s. net, or direct by post 2s. 1½d.

atmospheric impurity is highest, so that the doubt arises whether a subsequent rise of death rate may not be due to the cold rather than to the fog, and the Committee cautiously concludes that "on the whole there is no very obvious relationship between the quantity of impurity in the air and the number of deaths in London." This is a kind of question in which the experience of wide-awake practitioners of medicine as to the effects of fog and cold in setting up fatal respiratory attacks amongst the aged would afford valuable information, to be considered along with the observations and inquiries of the Advisory Committee. In a brilliant address given a good many years ago before the Sanitary Institute by that distinguished scientist the late Sir William Ramsay, much mischief was attributed to atmospheric smoke as directly limiting access of sunlight to manufacturing cities. Its influence on tuberculosis would naturally be thought of in that connexion.

For measuring suspended impurity in London three automatic instruments have been set up—one at South Kensington, another at Kew Observatory, and the third at Victoria Street, Westminster. Particulars, illustrated diagrammatically, are given regarding the observations at Westminster on foggy days, distinguishing week-days from Saturdays and Sundays, when industries and factories are mostly closed down. Curves of observations at the same station are shown for similar groups of days without abnormal fog. It is pointed out that certain features are common to all the curves. The air is purest between midnight and 6 or 7 a.m. A rapid increase of impurity begins about 6 a.m. on week-days, but about an hour later on Sundays. The maximum for the day is reached about 10 to 11 a.m. on week-days and 11 to 12 on Sundays. Then there is a rapid fall until a second, but lower, maximum appears about 4 or 5 p.m., which may continue till about 8 p.m.; after that hour there is a fall until the minimal period, beginning about midnight, is reached. The obvious relation of these curves to human activities is remarked on—the lighting of morning fires, the tea-time rise in the afternoon, and the night period when neither domestic nor factory fires are in operation. The difference between the week-day and week-end data is related to the absence of factory smoke. The ratio of factory to domestic smoke measured in this fashion was 1 to 2.25 at Westminster and 1 to 2.15 at South Kensington. In these parts of London, therefore, domestic smoke seems to be more than double the factory or industrial smoke. The observations refer to the period from October to March, the season when domestic heating is in constant action. Probably there is less seasonal difference in factory than in domestic firing, but that point is not discussed in the report. It is, however, pointed out that London is not a manufacturing city, and that the ratio in such a city would doubtless be different.

The number of stations throughout the country at which observations were made during the year was thirty-one. Of these, six were in the London County Council's area, three in Birmingham, one each in Newcastle, Hull, and Liverpool, and no fewer than nine in Glasgow. The preponderance of Glasgow is remarkable, but it would be unfair to assume that the figures represent the comparative prevalence of smoke in the places named, otherwise the absence of any station in Manchester would suggest its special suitability as a health resort. On the other hand, they cannot be taken as indicating the relative enthusiasm or success of the respective municipalities in the abatement of smoke, for in that case Glasgow might set up its claim for exceptional salubrity. The Lord Provost of that city, however, speaking as member of a deputation the other day to Sir Alfred Mond (we were not aware that Scotland is under his jurisdiction), claimed that in taking proceedings under the Scottish Act it is not necessary to prove,

as in England, that the smoke is "black," but only that it is a nuisance. This seems certainly an advantage. The Lord Provost is, no doubt, right in holding that the solution of the domestic problem is cheap gas and electricity, but it will, we fear, be a long time before the public and their landlords are persuaded to give up open fireplaces, and Sir Alfred Mond was careful to emphasize this doubt in his cautious reply to the deputation. He promised, however, to do his best to prevent the valuable report of Lord Newton's Committee from being pigeon-holed.

A NEW ANTIVIVISECTION BILL.

WE published last week (p. 492) an analysis of the provisions of a "Cruelty to Animals Bill" which Lord Lambourne has introduced in the House of Lords. We cannot believe that it will be allowed to pass through the House of Lords as it stands now, for to those who remember the final report of the Royal Commission on Experiments on Animals in 1912 this bill seems merely an attempt to reverse the position which was decided on ten years ago.

Lord Lambourne, when he was Colonel Lockwood, was a member of that Commission. He represented antivivisection, and his name was on the vice-presidents' list of one of the antivivisection societies, but we have reason to believe that it did not long remain there. He was very courteous throughout to the representatives of our science and art: and it is especially to be noted that he carefully stated, in the House of Commons, at the time of the publication of the Commission's Report, that the Commissioners, with regard to Dr. Crile's experiments in 1895, had carefully searched through the whole question and believed that the animals used in those experiments were absolutely senseless, and without pain. Antivivisection has said such things about those experiments that we are glad to recall this statement concerning them.

The Commission ceased to hear evidence early in 1908, but its final report was delayed till March, 1912. We can be sure that much of the delay was due to the desire for unanimity; indeed, Mr. Ram, who succeeded Lord Selby as chairman, was determined that the report should be unanimous. Anybody who will read the report now will observe how it slurs over much that it ought to state emphatically. This slurring is plainly due to the desire to bring all the Commissioners into line. Possibly this was the wisest course. Every one of the Commissioners signed the report. Though there was no minority report, three of them—Colonel Lockwood, Sir William Collins, and Dr. Wilson—signed the report subject to a memorandum, which was appended to it. The Commission recommended certain changes in the administration of the Act. These changes were duly accepted by the Home Office, which alone administers the Act. None of them involved any change in the wording of the Act, so that there was no need for legislation.

The Act, as we all know, is ill drafted, clumsy, and antiquated. It is forty-six years old. It became law in 1876, when there was virtually no bacteriology. It makes no provision for that study. Even now the Home Office has to schedule a bacteriological experiment under Certificate A, which is the certificate dispensing with anaesthetics: thus, many experiments which cause no pain, or are altogether negative, are still reckoned by some members of the public as "vivisection." The Act ought to have been simplified long ago. Still, the Commission was of opinion that "the present system, although open to adverse criticism which has been indicated, has nevertheless been so

worked as to secure a large degree of protection to animals subject to experiment, and at the same time so as not to hamper or impede research. Such a system, to which all the parties affected have by long experience become habituated, should not, in our opinion, notwithstanding its imperfections, be lightly thrown away. We believe it to be capable of improvement, and we have made several recommendations calculated, as we believe, more effectually to secure the objects aimed at by the Act."

The Commission therefore recommended: (1) That the inspectorate should be increased; that the chief inspector should be a whole-time officer, and that there should be in addition to him three whole-time inspectors for Great Britain. (2) That an inspector should be present at any experiment in which curare was used, and should satisfy himself that the animal, throughout the whole experiment and until its death, was in a state of complete anaesthesia. (3) That an inspector should have power to order the painless destruction of any animal which, having been the subject of any experiment, showed signs of obvious suffering or considerable pain, even though the object of the experiment might not have been attained, and that in all cases in which, in the opinion of the experimenter, the animal was suffering severe pain which was likely to endure, it should be his duty to cause its painless death, even though the object of the experiment had not been attained. (4) That an advisory body should be appointed by the Home Office, from a list of names submitted to the Home Secretary by the Royal Society and the Royal Colleges of Physicians and Surgeons in London, and that no person so elected should be the holder of a licence.

These recommendations were adopted by the Home Office, which for ten years has administered the Act wisely and carefully. Now comes Lord Lambourne's amazing bill. We call it his bill, but it seems the work of Mr. Stephen Coleridge at his worst. For example, it demands that the Home Secretary, in the granting of a licence, "shall pay special regard to the applicants' reputation for humaneness." That is Mr. Coleridge all over. Again, it demands that curare shall not be used or administered for the purpose of or during an experiment. That likewise is Mr. Coleridge all over. Professor Starling thoroughly explained to the Commission the use of curare, not instead of an anaesthetic, but for a specific purpose which would not interfere with perfect anaesthesia. This use of this very rare drug is absolutely painless. The Commission went too far in 1912, when it recommended special precautions about curare; and now Lord Lambourne would go a great deal further.

Now we come to a very bad fault of this bill. It proposes that "a licence shall not authorize the performance of more than one experiment, or one series of not more than six connected and consecutive experiments." In the testing of milk, the standardizing of drugs, and much work done for Government and various public bodies, many experiments are made; they do not involve any operation, but they are very numerous. For instance, to go so far back as 1908, no fewer than 12,500 observations were made for the Royal Commission on the Disposal of Sewage. Young fishes and fishes' eggs were exposed to the influence of effluents in different stages of purification and dilution. That is all that was done to them. Yet every one of these 12,500 observations was counted by the Home Office. With Lord Lambourne's bill that would require 2,083 licences. A worse fault of this bill is the demand that an inspector shall be present throughout the whole of any experiment involving an operation. This legion of useless inspectors would be in the way; they would do no good, and they would be a heavy expense to the tax-paying public. The worst fault in the bill, however, is the demand that no animal after operation shall be kept for observation.

When we look back over the past forty years of physiology and surgery in this country we see how this extraordinary demand is calculated to ruin our physiology and surgery in more ways than one.

Perhaps Lord Lambourne is planning to give way over some points, and to save enough of his bill to stir up the Home Office. That would please some of his advisers. But the Home Office is not likely to play fast and loose with the report of 1912. And we may doubt whether we shall hear anything more of this curiously perverse bill.

THE CONFERENCE OF HOSPITAL STAFFS.

In the SUPPLEMENT of this issue is published a full report of the proceedings of the conference of members of the staffs of voluntary hospitals held in London on March 22nd at the instance of the Council of the Association. The report of the Council on the organization of voluntary hospitals, published in the SUPPLEMENT of February 25th, was under consideration. The proceedings occupied a whole day, there was a good attendance, and the report is a sufficient indication of the keenness of the interest shown. The report of the Council is a long document, dealing with many matters of principle and detail, and that its fifty or more recommendations should have been considered seriatim in an open conference of hospital staffs from all parts of England and Wales, and approved by heavy majorities in all essential respects, is strong testimony to their general applicability. The keenest discussion centred around a few crucial recommendations. Chief amongst these was paragraph 33, or what is commonly known as the Leicester resolution, and until this was disposed of (at the opening of the afternoon session) the morning's debate tended again and again to turn to its subject. At the outset it was clear that the conference accepted without demur the paragraph recommending that "indigent" patients—those certified by the almoner or other officer of the hospital as unable to contribute in any way towards their maintenance and treatment—should receive hospital benefit through the gratuitous contributions placed at the discretion of the hospital managers and by the gratuitous services of the honorary medical staffs. There was no doubt of the complete unanimity of the meeting on this head. Further, the conference was unanimous in agreeing to the recommendation that when the Board of Management of a voluntary hospital enters into a financial arrangement with a public authority, an employer of labour, approved society, insurance company, or under a contributory scheme, or otherwise, for the reception of patients, such arrangements should be taken to cover the cost of maintenance and treatment, and a percentage of all such receipts should be passed into a fund which is at the disposal of the honorary medical staff of that hospital. There was thus complete agreement on the two extreme positions of the problem; it was on the intermediate position that difficulty arose. The point at issue was whether or no the part-paying patient should have the gratuitous services of the staff. On the one hand it was argued that to take a toll on the small payments of these patients would be mean, on the other hand that as a matter of principle a payment by a patient removed him by that degree from being a charity patient, and that unless this principle was recognized there would be no limit to the extension of part payments. The Leicester resolution was carried by a large majority (85 to 28). This is the fourth time this resolution has been submitted to a considerable body of the profession and carried; the three previous occasions were the conference of hospital staffs in December, 1920, the Representative Meeting in July, 1921, and the Conference of London hospital staffs in November, 1921. To judge by the speeches at the meeting last week, it would appear that the minority opposed to the resolution was mainly composed of representatives of the larger teaching hospitals. There is little doubt that members of the staffs of these hospitals are in an exceptional position as compared with their colleagues at other voluntary hospitals to which medical schools are not

attached. Nevertheless, not a few members of the teaching hospitals argued forcibly for the necessity and justice of this recommendation. The definition of the voluntary hospital gave rise to a brisk debate not unrelated to the foregoing considerations, but little was said beyond what has appeared in a recent correspondence in our columns. The sections of the report dealing with the new matter of contributory schemes were received with a remarkable degree of unanimity, particularly the recommendation that no insurance risk should be taken by the hospitals themselves, lest it should limit their independence in the selection of patients and involve the diversion of the charitable funds of the hospital; so also was the recommendation that consultation and specialist-services under such schemes should be arranged at the homes of the doctors or patients, and not at out-patient departments. There was some criticism of the classification of patients under the terms: Free (indigent), Tariff, and Private, but it was finally accepted as the simplest and most explicit. Certain recommendations dealt with the more intimate relations of the members of hospital staffs themselves, and these had varying fates. Some that appeared to trench upon the prerogatives of the staffs were rejected; but a recommendation that the age limit or tenure of office of members of honorary staffs should where necessary be so modified as to allow more and younger practitioners to obtain responsible hospital experience received a very generous reception and was agreed to unanimously. This is the third conference of hospital staffs which has been called by the Association, and the response thereto on this, as on former occasions, indicates that the opportunity for these open discussions is greatly valued.

CALCUTTA SCHOOL OF TROPICAL MEDICINE.

THE School of Tropical Medicine and Hygiene and the Carmichael Hospital for Tropical Diseases at Calcutta were opened by Lord Ronaldshay, Governor of Bengal, on February 4th. In our issue of December 3rd, 1921 (p. 957), it was noted that the School of Tropical Medicine and Hygiene had begun work in the previous November, when a telegram of congratulation, announcing that the first lectures had been given, had been sent by the director, Lieut.-Colonel J. W. D. Megaw, I.M.S., to Sir Leonard Rogers, who played the leading part in the inception and carrying through of this great enterprise. In the JOURNAL of April 23rd, 1910 (p. 1010), the very great advantages which Calcutta offered for the establishment of a school of tropical medicine were pointed out; not only is the variety of clinical cases illustrating tropical diseases unsurpassed, but there is an excellent hospital and medical school, with a highly qualified staff accustomed to teaching, and for the greater part of the year the climate is no drawback. Some eleven years ago the general scheme for the school of tropical medicine was worked out by Sir Leonard Rogers, but its subsequent history has been marked by many delays, not a few of them to be traced to the war; the foundation stone was actually laid by Lord Carmichael, Governor of Bengal, in February, 1914. The hospital has accommodation for about 100 patients, European and Indian, while the school has chairs of tropical medicine, pathology and bacteriology, protozoology, pharmacology, serology, public health, and chemistry, to which appointments have already been made; professors of hygiene, entomology, and biochemistry have still to be appointed. In addition, there are assistant professors of the chief subjects, and a number of special research appointments have been made. The nucleus of a reference library has been formed, mainly by gifts from Sir Leonard Rogers. In the report of the director for 1921 it is stated that classes will shortly be opened for the diploma in public health of Calcutta University; classes for the diploma in health of Calcutta University have already begun. The director considers that the result of the first year's working has entirely removed the doubts and fears which assailed him when he entered on his responsible duties. Considerable progress has also been made in the research laboratories, and reports have

been published of work in connexion with leprosy and kala-azar and filariasis, and on the work of the hookworm laboratory.

THE SPECIAL SURGICAL HOSPITAL, SHEPHERD'S BUSH. THE decision to retain the Special Surgical Hospital for wounded soldiers at Shepherd's Bush, instead of removing it to the huts recently occupied as the South African Military Hospital in Richmond Park, will be received with widespread satisfaction. It was generally thought that no other course was possible in view of the debt which we owe to the men who are still suffering from injuries inflicted during the war. As the dispute between the Ministry of Pensions and the Hammersmith guardians has been settled, the actual terms of the agreement are of little consequence. We all recognize the necessity for economy, but nothing would have justified the practising of an economy at the expense of these ex-service men who still are in need of treatment. During last year nearly 4,000 officers and men were under treatment in the hospital, nearly 2,500 operations were performed, and there was a total of over 101,000 out-patient attendances. There are thousands of wounded men still under treatment, many of them grievously injured, and it is clearly the duty of the country to do what is best for them. For the sake of these men we rejoice that a way out of the deadlock has been found and that the hospital, with its elaborate equipment of baths, gymnasiums, workshops, and departments for electrical treatment and massage, will be allowed to continue its most necessary and beneficent work. The settlement which has been reached cannot, however, be considered as final. It is essential to look forward to the time when some permanent provision will have to be made for those wounded men who may from time to time need operation or treatment, after the present buildings have had to be given up. A hospital with a large out-patient department will be needed. The country will not tolerate any attempt to treat these chronic and mostly incurable cases under conditions which would not for a moment be sanctioned for a Poor Law infirmary. The problem is by no means an easy one, but unless those in authority exercise foresight, no adequate provision will, when the time comes, have been made for the suitable housing and proper treatment of those ex-service men whom we are bound in honour to care for as long as they are in need of help.

THE DANGERS AND LIMITATIONS OF SALVARSAN. THE full dress debate on salvarsan at the Berlin Medical Society, which took place on January 25th, and which is reported in *Deutsche medizinische Wochenschrift* for February 16th, was marked by a certain reticence on the part of speakers conscious of the agitation against salvarsan in the daily press and of the likelihood that admissions of failures and disasters would be relentlessly exploited by the lay critics of salvarsan. One of the speakers, Arndt, admitted that although every precaution had been taken, there had been several waves of fatalities. He himself had observed only four deaths between 1914 and 1918; in 1919 he had seen none, and in 1920 he had again seen none, although he had given 24,000 injections in that year. But in 1921, during which year he had given 14,000 injections, he had had eight deaths. With regard to the frequent occurrence of acute or subacute yellow atrophy of the liver, he said that most of the patients were over 40, and that salvarsan jaundice was most common in connexion with tertiary syphilis. Owing to salvarsan fatalities the dosage had been reduced, and the exhibition of the drug had been limited in the main to primary and secondary syphilis; these two precautions had practically eliminated salvarsan jaundice. He was inclined to treat almost every case of tertiary syphilis with iodine and mercury only. The results they produced were quite satisfactory. He never gave more than 0.45 gram to men nor more than 0.3 gram to women at one injection, and his total dose for men and women was 4.0 and 3.6 gram respectively. He had often observed

a change in the temperature curve as the only sign of impending salvarsan poisoning, and he took this sign as an indication for immediate cessation of treatment. Recent improvements in the manufacture and control of salvarsan were discussed by Kollo of Frankfurt. The control, he said, was becoming closer, and a keen watch was kept for specially neurotropic consignments of salvarsan by biological tests on rats. He believed, however, that the angio-neurotic complications of salvarsan preparations were mainly due to the metallic salts they contained, and as these properties could not well be tested on animals, it was necessary to test consignments of salvarsan clinically; when they betrayed these undesirable properties after the administration of small doses the particular consignment concerned would be withdrawn from the market. He referred to the detoxication of salvarsan by the addition of a 40 per cent. solution of grape sugar (*Epitome*, February 4th, 1922, No. 102), but he had grave misgivings as to the wisdom of combining salvarsan with mercurial injections. Of the various salvarsan preparations, neo-silver-salvarsan had impressed him most favourably, and experiments on animals with salvarsan alone, and salvarsan plus mercury, had shown him that within thirty days of infection a *sterilisatio magna* was feasible in 100 per cent., as shown by the animals' susceptibility to re-infection. But ninety days after infection not a single animal was cured. Both these speakers, it will be observed, emphasized the value of salvarsan early in syphilis and its comparative futility late in the disease.

PROFESSIONAL PROTECTION SOCIETIES AND INCOME TAX.

FROM inquiries which have reached us it is clear that there is some doubt as to the admissibility, as deductions for income tax, of payments charged in the statement of professional expenses in respect of subscriptions to societies whose purpose it is to assist the medical practitioner in defending himself from attack. The growth of this form of co-operation has now covered almost the entire professional and industrial field, and in the case of large commercial concerns considerable amounts are sometimes involved. It is, of course, clear that in such cases the subscriptions may be intended to serve many objects, some of which—for instance, the provision of a pool of profits for distribution among the members during strikes or lock-outs—may not provide legitimate grounds for treating the payment as an expense proper to an income tax calculation of profit. The leading case on the point is known as the *Lochelly Iron and Coal Company, Limited, v. Crawford*; the effect of the decision in that may be said to be that so much of each subscription may be deducted as represents the portion expended on objects which would have been good ground for a claim by the individual member if he had made the payment direct; in other words, the subscription must be divided according to the legitimacy for income tax purposes of the ultimate expenditure. If, for instance, 25 per cent. of a medical defence society's subscriptions for 1921 is expended in building up a reference library or some other object involving "capital" outlay, and the remaining 75 per cent. is spent on defending the professional conduct of its members, then under the *Lochelly* decision each member can claim to deduct 75 per cent. of his subscription. One or two minor points may be mentioned. It will be seen that it is not necessary to trace the expenditure of any individual subscription—an impossible task. The judges in the *Lochelly* case seem to have accepted as a matter of course the idea that the proper basis was furnished by the aggregate expenditure, without inquiring as to how the *Lochelly* company itself actually derived any benefit. Also it has to be borne in mind that this case related to Schedule D; it is probable that under the stricter Schedule E rule no such allowance would be upheld in the courts. In the third place, although a substantial portion of the subscriptions of industrial and commercial concerns may be held up for future contingencies or more directly applied to "capital" purposes, as distinct from being applied on revenue

account, that consideration has little force as applied to professional societies. Consequently it is likely that there would normally be a smaller percentage open to rejection by the income tax authorities; seeing that the annual subscriptions are comparatively small it is not a matter for surprise that in many cases local inspectors regard the matter as covered by the maxim *de minimis*. Nevertheless the point is sometimes raised, and a brief statement of what we understand to be the practice may be of some utility. The difficulty of the *Lochelly* decision lies in its practical application. It will be realized that the allowable percentage of the subscription depends on matters of some complexity, which can adequately be dealt with only after detailed examination of the accounts of the society. In these circumstances the Board of Inland Revenue—as was explained by official witnesses before the Royal Commission—have entered into "arrangements" with various societies, the essence of which is that the Board agrees to the allowance to the members of their individual subscriptions, and the society acquiesces in assessments made upon itself on the basis of the excess (if any) of its receipts over its expenses so far as these are legitimate for tax purposes. Where such an arrangement is not made the society cannot be assessed for the excess of subscriptions over its expenses because it is not legally assessable, but, on the other hand, each individual member may be called upon to prove what proportion of his subscription is allowable under the *Lochelly* decision. The practice in question seems not unreasonable, and was apparently so regarded by the Royal Commission, but where the subscriptions are so small that the non-allowable percentage is already covered by the practice *de minimis* no useful purpose would be served by taking any action to bring any particular society within the "arrangement" provided by the Board of Inland Revenue.

JOHN FERRIAR, M.D.

ALTHOUGH a pioneer in preventive medicine, a most able critic, a poet of no mean parts, an antiquarian, and an essayist, John Ferriar's (1761–1815) name is now little known to members of his profession. His life in the *Dictionary of National Biography*, by a lay hand, deals chiefly with his contributions to general literature, and in a scholarly account of this interesting personality Dr. John Ruhrah¹ of Baltimore remarks that "few physicians to-day who do not lean to literature have ever heard of Ferriar." There is, however, a full account of his life, with much detail about his endeavours to improve the sanitary condition of Manchester in order to prevent the ravages of typhus, in Dr. E. M. Brockbank's *Sketches of the Lives and Work of the Honorary Medical Staff of the Manchester Infirmary*, to which Ferriar was honorary physician from 1790 to 1815, and where a small ward bears his name. Born at Oxnam in Roxburghshire and medically educated at Edinburgh, Ferriar began practice at Stockton-on-Tees in 1782, but three years later he moved to Manchester, and at once became active with his pen; in 1785 he produced papers on "Popular Illusions and more particularly of Modern Demonology," and "On the Dramatic Works of Massinger"; in the following year he turned out no less than five papers dealing with antiquarian, theological, and physiological subjects. In 1788 he published *The Puppet Show, a Didactic Poem*, and his best known work, *Illustrations of Sterne, with other Essays and Verses*, of which Dr. Ruhrah says that "it is easy to read and may be recommended to every lover of Sterne and to every hater of Sterne—there are some such stupid people in the world—so it must give endless satisfaction." In it Sterne's plagiarisms from the old French novelists, Bishop Hall's sermons, and from Burton's *Anatomy of Melancholy*, are incidentally shown up; but Dr. Ruhrah pleads that nearly all great literary lights have done likewise, and that Sterne improved whatever he borrowed, making it sparkle and giving it a worthy setting; so that the reader will appreciate Sterne's version more highly than Burton's.

¹ *Ann. Med. History*, New York, 1921, iii, 343–353.

original; and he remarks that Ferriar points out the service thus rendered and he dedicates an appreciative sonnet to "Sterne, for whose sake I plod thro' miry ways." Ferriar's "The Bibliomania, an Epistle to Richard Heber, Esq.," contains many fine lines, and was followed by *The Prince of Angola*, a tragedy. Of his medical works, the most substantial was *Histories and Reflections*, in three volumes (1792, 1795, and 1798), to which a fourth volume was added when a second edition appeared in 1810-13. *An Essay on the Medical Properties of Farglore*, from his pen, saw the light in 1799, but the best of his professional contributions, one that, to quote Dr. Ruhrah, reads like a novel, or rather like a collection of modern short stories which any mystery magazine could publish with but few changes, is entitled *An Essay towards a Theory of Apparitions*, and appeared in 1815.

ANAPHYLAXIS AND ANAPHYLATOXINS.

At the meeting of the Royal Society on March 16th Drs. H. H. Dale, F.R.S., and C. H. Kellaway presented a paper dealing with the two main theories put forward to explain anaphylaxis to a soluble foreign protein—namely, the theory of cellular antibody, and that of anaphylatoxin. They produced new evidence in favour of the first theory. A purified, concentrated precipitin for crystallized egg-albumen was prepared, and a control preparation was made of similarly concentrated globulin from normal rabbit's serum. Guinea-pigs were rendered passively anaphylactic to egg-albumen by an injection, two days previously, of the precipitin. Intravenous injection of a further dose of the same precipitin, given a few minutes before a dose of egg-albumen, suppressed the anaphylactic reaction completely; normal rabbit globulin showed no trace of such protective action. Similarly, isolated plain muscle from anaphylactic guinea-pigs, suspended in saline solution, was completely protected from the stimulating effect of egg-albumen by adding to the bath the precipitin which caused the anaphylactic condition; normal globulin had no protective action. The nature of so-called "anaphylatoxins" produced by digesting serum with carbohydrate sols, etc., was examined, and evidence was obtained that their toxicity is due, not to protein cleavage, but to formation of complexes which keep the foreign colloid finely dispersed in the finished product. The anaphylatoxins produce symptoms which are not identical with those of true anaphylactic shock, and do not act on isolated plain muscle as the anaphylactic antigen does, but only exhibit their action in the presence of the circulating blood. Their action is attributed to exposure of the blood to a large foreign surface. One dose of anaphylatoxin renders an animal insensitive to another, but leaves it, if anaphylactic, sensitive to the antigen.

THE RUSSIAN EPIDEMIC MENACE.

A CONFERENCE, called at the instance of Poland by the League of Nations to concert measures to prevent the spread of typhus fever and cholera westward from Russia and the border countries, was opened last week in Warsaw. The *Times* correspondent states that twenty-three countries were represented, including Turkey, Germany, and Soviet Russia. Great Britain was represented by Dr. S. P. James, of the Ministry of Health. Three subcommittees were appointed—one to study the epidemic conditions in Russia and the neighbouring States, another to examine the measures taken or contemplated by the several Governments, and a third to recommend means to prevent the epidemics from spreading westward. It is from Western Russia that the chief peril to the rest of Europe comes, and the Ukrainian Red Cross reports that in the south-west the conditions are terribly bad. Both typhus and typhoid fever, which were prevalent in December, were more widespread in January, and are believed to have increased since. It is expected that under the impulsion of famine the people will endeavour to migrate westward as early in the spring as the roads become passable. As to the interior of Russia, what has already been published from time to time with regard to the condition of medical

affairs and the medical profession may be supplemented from a paper recently contributed to the Danish *Ugeskrift for Læger*, the journal of the Danish Medical Society (February 2nd, 1922), by Dr. J. W. S. Johnsson. He writes of "the systematic extinction of Russian scientists," and bases himself on statistics contained in a journal called *Rul*, published in Berlin. Deaths by execution are, he says, printed in one list and deaths by starvation and disease in another. In *Rul* (No. 283, for October 21st, 1921) the first list contains "only" 22 names, while there are 78 in the second list. It is stated that the gynaecologist, Professor Fenomenow of Petrograd, has died of starvation, Professor Brinno was shot in Kiev by the Bolsheviks, and Professor Ott, one of the most notable Russian gynaecologists and the Tzarina's personal medical attendant, has died in the Caucasus in the greatest poverty. It would seem that Kiev was the scene of the worst atrocities and executions, and that Petrograd and Moscow come next. The death of Dr. Farrar from typhus in Moscow last December will be fresh in the minds of readers, and recently Professor Nansen stated that he had lost two of his assistants, the Swedish expedition a nurse, the Quakers two of their men, and the Germans one. He estimates that during the past two years about twenty million Russians have suffered from typhus fever, but as the recorded mortality was only about 1 per cent, either the total is over-estimated or the number of deaths under-estimated. Professor Nansen anticipates a serious outbreak of cholera in the spring, and stated at the beginning of this month that the disease had already broken out in the Ukraine.

PSYCHOLOGY IN INDUSTRY.

A MEETING in support of the newly incorporated National Institute of Industrial Psychology was held at the Mansion House, London, on March 27th. Dr. C. S. Myers, F.R.S., who is retiring in June next from the directorship of the Cambridge Psychological Laboratory in order to act as director of the Institute, submitted a resolution emphasizing the need for applying its methods and aims to the better utilization of the human resources of the nation. Dr. Myers said that the Institute, even thus early in its career, had received the thanks not only of employers but of employed. A system of vocational selection was being recommended to employers, not as a substitute for, but as supplementary to, the ordinary interviews with candidates for posts, and as a means of assigning to each worker the most suitable task. He dwelt upon the growing appreciation of industrial psychology in the United States and in Germany. The latter country, where both employers and trade unions were realizing the value of such guidance, seemed likely in the future to exalt the human factor as much as in the past it had exalted the material. Vocational psychology was like medicine and surgery in that it depended upon both research and practice. He instanced the work of the scientific committee of the Institute, which, among other investigations, had occupied itself with the effect of atmospheric conditions on mental efficiency, the measure of mental weariness by means of changes in the span of apprehension to groups of sounds, the acquirement of motor habits, the intellectual and emotional development of adolescents, the tests of physical fitness and determination of standards (this last under the direction of Professor A. V. Hill), and variations from the normal of pulse and reflexes through fatigue (the work of Dr. B. A. McSwiney). Among those who spoke in support of the resolution—which, of course, was carried—was Viscount Haldane, who said that although the word "psychology" was suspect in many quarters, the sphere of psychology with which the Institute was concerned did not embrace those fascinating studies of the subconscious, such as dream phenomena, but was limited to a very simple method of applying exact observation in industry. The new science of psychology, which was really the application of an old science, came to the assistance of physiology at many points, and he believed that its pursuit would help to break down the common distinction, so often confusing, between brain work and manual work. He hoped to see the labour

of a man conceived as a single thing, not split up into arbitrary divisions which had little correspondence with reality. We may respectfully express the hope that the new psychology will be applied in some way to public speakers, so that they may adjust their voices to acoustic conditions; the noble Viscount's remarks cannot have been heard beyond the small semicircle in front of him, and the hall contained several hundreds of people.

CHEAPER SPAS.

ONE result of the formation of the British Spa Federation appears to be an effort to reduce the cost of visiting British spas. Dr. Fortescue Fox, in a letter published at page 542, makes two points: the one is that British spas have not made arrangements to meet the needs of persons of moderate means. The rich patient can go to an hotel, and at many of the spas there is a hospital, or more than one, for patients whose financial position entitles them to free or assisted treatment. The suggestion is that pensions or hostels should be established for such persons; this would have the double advantage of enabling them to visit the spa without unduly straining their resources and, while there, of being provided with a diet suitable to their state of health. At many foreign spas, especially in Germany and Austria before the war, pensions, with rates adapted to shallow as well as deep purses, were always provided by private enterprise, and there seems no reason why this should not be done in this country. Diet is often, perhaps usually, an important part of the treatment at a spa, and at many foreign spas medical regulations are rigidly enforced. The same is, we fear, not true of most British spas, where a patient may even have difficulty in obtaining in his hotel or pension the diet prescribed by his medical advisers. The other point is as to railway fares; Dr. Fortescue Fox calculates that it may be cheaper to visit a French or Swiss spa than to make the journey from London or the South of England to Scotland. Representations on this head have been made by the British Spa Federation to the railways. In some foreign countries the spas are subsidized by the railways, but in this country the railways seem to be bent on making as much as possible out of patients desiring to travel. The spas embraced in the federation have, we are informed, reduced the prices of mineral water and of various other medical treatments, and steps are being taken to induce hotels and other interests to fall into line with this effort to encourage the use of British spas by British patients. We hope that the railway companies will reconsider their charges and arrangements.

PUBLIC HEALTH TRAINING IN AMERICA.

CONTEMPORANEOUSLY with the revision of training and examination for the Diploma in Public Health in this country, the subject is being discussed in connexion with the medical schools of the United States. A conference of academic authorities was arranged to take place at Washington in the middle of March to discuss the future of public health in the United States and the education of sanitarians. The chief subjects on the programme for discussion on the first day, when Dr. William H. Welch was to be in the chair, were the present state of the education of sanitarians, and some of the newer aspects of public health, such as mental and child hygiene, physical education, and industrial hygiene. The second day was devoted to a consideration of the kind of sanitarians needed for the future and how they can be recruited. On the third day the chief subject was the training of sanitarians. In a circular announcing the conference the Bureau of the Public Health Service of the United States draws attention to the rapid development of the public health movement, the shortage of trained officers, and the inadequate facilities for their education, and states that "there has never been so much interest among people generally in public health"; it is held that with a sufficient supply of trained officers it would be possible "to immeasurably increase the health, efficiency, and happiness of the American people." Last

year the American Public Health Association, which includes Canadian members, appointed a committee to consider the standardization of public health training. In its report the pressing need for standardization is demonstrated in two tables containing a list of the universities and schools giving diplomas in public health and indicating the previous training, and the time to be devoted to special study for each. For the highest, that of Doctor of Public Health, when conferred by Yale, Harvard, Johns Hopkins, Columbia, and other schools of high repute, at least two years of special study are required, and the candidates must be graduates in medicine. But there are marked differences, and the Public Health Association's Committee states that the most serious defect in the whole system at present "lies in the fact that certain institutions give not only the certificate in Public Health, but even the doctorate in Public Health for a course of a few weeks, while others require a period of almost three years, and it seems most desirable to effect some form of standardization in this field." One remarkable body, indeed, requires only a thirty-six hours' course, but it is explained, as regards previous training, that there are "no recent data available" for the body in question, which has its headquarters in Chicago; it must be a law to itself, and its degrees are no doubt valued at their real worth. Other diplomas granted by various institutions are Doctor of Philosophy in Public Health, Bachelor of Science in Hygiene or Public Health, Certificate in Public Health (C.P.H.) in Industrial Hygiene, in Nursing, and in quite a number more. Canada has evidently followed the lead of the old country, for its medical schools instead of a Dr.P.H. give a D.P.H., always based on a degree in medicine, though the period of special study appears to be shorter than for some of the doctorates in the States. From the documents before us it is evident that the whole subject is being thoroughly considered. Meantime the Committee recommends *inter alia*, "That the authorities having the appointment of health officials be urged to give preference so far as possible to persons holding degrees or certificates in public health or hygiene."

We regret to have to record the death of two veteran members of the British Medical Association: Dr. Charles Parsons, formerly of Dover, died at Tunbridge Wells on March 24th; he had reached his 90th year; he was Treasurer of the Association in 1896-98. Dr. W. Ainslie Hollis of Hove died there at the age of 82 on March 26th; he was President of the Association when it held its annual meeting in Brighton in 1913.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

Nurses' Registration.

A DEBATE was raised on March 22nd on the proposed new rules of the General Nursing Council for England and Wales, with special reference to Rules 9a and 43 (2). Rule 9a provided that the Nursing Council might receive for purposes of registration a certified copy instead of the certificate itself. Major Barnett, who moved an address to His Majesty that the rules should be annulled, said that in order to secure a uniform standard of qualification in all parts of the United Kingdom the Act required the English Council, before making any rules as to the conditions of admission to the register, to consult the Nursing Councils of Scotland and Ireland. The Scottish Council had not been consulted as to this rule; it had written to the English Council asking that the rule should be withdrawn, and, pending the adjustment of the matter, had not passed any rule to allow registration of the English nurses on the Scottish register. Sir Alfred Mond replied that he was acting in accordance with the opinion of his legal adviser, and that the rules were purely a matter of machinery, which did no more than prescribe the evidence which nurses were to produce of their qualifications. He had consulted the Scottish Council on several occasions, and on each would do so again; but it was absurd to suppose that the English Nursing Council and the Minister responsible was incapable of carrying out the Act in England except by the consent of the Scottish Nursing Council. There was what he described as a long feud between two nursing associations. Out of some 50,000 nurses 19,000 were on the register of the College of Nursing; under the rule the Registrar of the English Nursing Council would examine copies of the certificates of the College of Nursing to satisfy himself when an application was made, and the same would be done with the other associations; there would be no favour to anybody.

The reason he was taking this action was that since November, when the register came into existence, 3,235 actual cases had been received and only 984 completed. Applications were coming in at the rate of 800 a month, and less than one-third had been finally passed by the Council. The present Council must, according to the Act, come to an end not later than November 23rd next. Out of 50,000 nurses there were only 1,500 on the register, and unless by November 23rd next a large number were enrolled there would be the absurd position of the election of the Council for three years by quite an inadequate number. It was impossible for the chairman of the Registration Committee to go into long details of every one of these certificates and cross-examine in every case. If he did so, many of the nurses would be dead and buried before they got on the register. The Nursing Council had passed this rule by a majority of 16 to 6. The Matrons Association of Great Britain, representing the matrons of the leading London and provincial hospitals, was entirely in favour of the rules; if they were rejected there would be no other course open for him but to move the repeal of the Act, so doing away with the register altogether.

The debate was continued by Mr. R. Richardson, Mr. Lyle, and Captain Elliot, who said that the broad object of the section of the Act was not being fulfilled by the rules. The prime consideration was that the two registers in Scotland and England should be similar and parallel in all respects, and that object was not being attained. The protests from the Scottish nurses had not come from any one section, but from the body legally set up under the Act.

Major Barnett claimed a division, and his motion was rejected by 61 votes to 49.

Smuggling of Drugs into England.—Replying to Mr. Morris, on March 27th, Mr. Shortt said that information was received from time to time that opium, cocaine, and other drugs were smuggled into this country, or sent through the post from the Continent, and it was known that Chinese seamen and others were addicted to the opium habit, but the police were not aware of any organized traffic. Every effort was made to detect offenders, but short of opening all incoming passengers' luggage, the minute search of every passenger, and the examination of every postal package, it would not be possible to suppress entirely the illicit introduction of drugs into this country as long as it was possible to obtain them without difficulty in other countries. International co-operation was essential, and the question was engaging the attention of the League of Nations, which had been entrusted by the treaties of peace with the general supervision of the traffic in opium and other dangerous drugs.

Health Services: South Wales.—Mr. T. A. Lewis asked, on March 27th, whether the report of the South Wales Regional Survey Committee had yet been considered by the Ministry of Health, and whether there was a prospect of any of the recommendations being put into operation. Sir A. Mond said the valuable report of the Committee had been carefully considered, but the present was not an opportune time for adopting special measures for carrying out the recommendations of the Committee.

Medical Establishment, Territorial Armies.—Lieut.-Colonel Fremaux asked, on March 23rd, what would be the total number of officers and of other ranks on the peace and war establishments respectively of the several medical units of the Territorial Army on effect being given to the proposed economies; what would be the peace and war establishments of medical officers on the Headquarters Staff of a Division; and whether it was proposed to give generous compensation to D.A.D.'s.M.S. of the Territorial Army on the premature termination of their appointment. Sir L. Worthington-Evans regretted that the details of the establishment were not yet sufficiently settled to enable him to publish them. The Deputy Assistant Directors of Medical Services were given two months' notice of abolition of appointment from March 1st, 1922, and they would continue in receipt of full pay and allowances of the appointment up to April 30th, 1922, inclusive.

The Medical Services for the Air Force.—On report on the Air Estimates, Dr. Murray, on March 23rd, inquired as to the reduction in the items of medical services. The amount for 1921-22 was £141,800. The amount for 1922-23 was less by £58,400. Captain Guest, in reply, said that there was a big reduction in payments to hospitals. In 1921-22 these payments amounted to £132,500, but the estimate for 1922-23 was £73,000. This was largely due to a new system in the Royal Air Force of dealing directly with big civilian hospitals instead of keeping up expensive establishments of its own.

Disability Pensions for Tuberculosis.—Mr. Macpherson informed Mr. Tillet, on March 23rd, that cases of tuberculosis, as of other disabilities, would be considered for final award in accordance with the provision of the Act of 1921 as early as possible. He was advised, however, that each case of tuberculosis must be considered on its merits, and that having regard to the nature of this disease, it would not in all cases be in the best interests of the pensioner to make a final award.

Contagious Disease in Uganda.—Mr. Churchill, in answer to Mr. Hailwood, on March 22nd, said there was no analogy between the Contagious Diseases Acts formerly in force in England and the measures which had been in force in Uganda since 1913 for preserving a population ravaged with venereal disease. The question whether the procedure in Uganda could be improved in detail, and whether special reference to prostitutes could be deleted from the legislation without relieving that class from the examination considered necessary in the case of the general population would be referred to the Governor. He was satisfied, as was Mr. Harcourt in 1913, as to the need for drastic action in

dealing with the matter. The main legislation on the subject was a native law of the kingdom of Baganda, passed by and at the instance of the native government; and the administration was a matter for the native chiefs and not for the British officials; though the Government medical officers gave their services in examining the suspected cases sent to them by the chiefs. Corresponding legislation existed to cover the case of those not subject to the native law.

Treatment Centres for Ex-Service Men in London.—Major Tryon informed Mr. Gilbert, on March 16th, that there are five hospitals and nine special medical clinics maintained by and under the direct control of the Ministry of Pensions within the administrative County of London. These are as follows:

Hospitals:

Chinoh Lane, Tooting.
Ducane Road, Shepherd's Bush.
Lonsdale House, Clapham Park.
Ruskin Park, Denmark Hill.
"Fernbank," Roehampton.

Special Medical Clinics:

Cheltenham Terrace, King's Road, Chelsea.
92, Dalston Lane, Hackney.
St. Paul's Schools, Queen Street, Hammersmith.
12a, Lyndhurst Road, Hampstead.
Regent Street Polytechnic, 14, Langham Place, Regent Street.
6, Hatherly Grove, Paddington.
11, Palace Green, W.I.
The Hut, Morpeth Terrace.
23, Nightingale Place, Woolwich.

In addition, the Ministry is making use of some fifty civil hospitals and treatment centres in London at an agreed charge for each patient. The number at present receiving treatment at these institutions is approximately 21,000. There is no immediate prospect of closing down any of the institutions in the London County area, though that prospect is kept constantly in view.

Illegitimacy Statistics.—At the instance of Mr. G. Murray, Sir Alfred Mond, on March 14th, circulated the following comparative statistics of illegitimacy in various countries:

	1913.		Latest Available Figures.		
	No.	Rate per 10,000 of Total Live Births.	Year.	No.	Rate per 10,000 of Total Live Births.
England and Wales...	37,909	430	1920	44,947	469
Scotland ...	8,518	709	1920	10,201	747
France ...	65,558	879	—	—	—
Belgium ...	10,975	641	—	—	—
Holland ...	3,591	207	1922	4,112	213
Norway ...	4,360	714	1917	4,465	699
Sweden...	20,160	1,548	1916	18,125	1,450
Denmark ...	8,313	1,147	1919	7,170	1,013
Italy ...	52,219	465	1916	35,881	418

Viewing the Body at Inquests.—On a question by Mr. Rendall as to the Coroners Bill which the Government had undertaken to introduce to replace the temporary law, Mr. Shortt promised that in framing the measure he would consider a proposal to make viewing of the body by the jury at inquests optional except when the coroner held that they should view it. There were, he said, strong reasons why the body should be viewed by the coroner, but the whole question would be carefully considered.

Medical Treatment of School Children.—In the debate on the Consolidated Fund Bill, on March 28th, Mr. Fisher warmly repudiated a suggestion from the Labour benches that the Education Act of 1910 was a dead letter; only three of the clauses in that measure had not been brought into operation. He referred with especial pleasure to the medical treatment of children, and claimed that there had been a great increase in efficiency.

Accidents in Factories and Workshops; Remarkable Statistics.—Sir John Baird, in an interpellative assertion by Lord Henry ... number of preventable accidents in factories and workshops during the year 1920 had increased by 12,750 over the number for the previous year. The figures referred, he said, to the increase in the number of reported accidents, and it was doubtful how far this number represented an actual increase. The number reported for 1919 was surprisingly low having regard to the trade activity of that year, and there was reason to think that there had been great laxity in reporting accidents during that period. The number of accidents fluctuated considerably from year to year according to trade activity and other circumstances, and an increase in one year might be followed by a corresponding or greater reduction in the following. This is what had actually happened in 1921: the rise of 12,750 in 1920 had been followed by a fall—due, no doubt, partly to trade depression—of over 46,000. The Factory Department was not relaxing in any degree its efforts to improve safety conditions in factories.

Answers in Brief.

The Minister of Health has stated that statistics of the number of persons who registered their names with a doctor under the Insurance Acts but did not have recourse to his services in case of illness were not available, but there was no reason to suppose that the percentage was considerable.

Several questions have been addressed recently to the Minister of Health with regard to legislation for the control of milk. Sir Alfred Mond, while expressing his appreciation of the importance of pure milk, has stated that it was equally important to avoid action tending to decrease the production of milk and increase its price to the consumer.

PROFESSIONAL SECRECY.

RESUMED DISCUSSION IN THE MEDICO-LEGAL SOCIETY.

THE discussion in the Medico-Legal Society on "Professional secrecy," which was opened on March 21st and adjourned, was resumed on March 28th, when Lord JUSTICE ATKIN again presided over a large attendance. The report of the first part of the discussion, including Lord Dawson's opening speech, appeared in the BRITISH MEDICAL JOURNAL of March 25th (page 494).

SIR LENTHAL CHEATLE raised the question of typhoid carriers and diphtheria carriers, and urged that the State, by requiring the notification of certain infectious diseases, had absolved the doctor from his professional secrecy in these respects. Doctors and midwives also were required to notify gonorrhoeal ophthalmia. He hoped that any legislation which was proposed for giving the doctor a certain amount of privilege would not embarrass the more perfect control of public health.

DR. R. LANGDON-DOWN thought that the two recent rulings of the court to which Lord Dawson had drawn attention—one in which the director of a venereal clinic was required to disclose, and the other in which a doctor had to produce evidence of notification of birth—although they raised points to which objection might be taken on other grounds, had not been shown to have any bearing on the principle which was to govern disclosure of medical secrets, and they afforded no evidence that the measure of privilege accorded in practice had been cut down. If they agreed with Lord Dawson that there was a limit to the obligation of professional secrecy, then the public should be made fully and clearly aware of this, so that medical men should not be open to the charge of dishonourable conduct when it became their duty to disclose. If they allowed the public to think that confidence was absolute, the public would be rightly aggrieved when it had to be admitted that confidence was limited, and the doctor had to give evidence. No proof had been forthcoming that the requirement of professional disclosure, which had operated for 150 years, had had any effect in sapping the confidence of patients in medical men. Would it not be possible to formulate some principles to govern the limitations as to secrecy? The first, in his view, should be that the rule of secrecy must be departed from in order to prevent injury—which he took to cover injustice of a grave nature—to the patient, other persons, or the State. If the threatened injury was direct or immediate it might justify spontaneous action by the doctor *a fortiori* under legal order. When the threatened injury was remote, contingent, or indirect, departure from the rule could only take place, if at all, in obedience to the law, whether embodied in Act of Parliament or the direction of the court. Generally speaking, if the principle of limitation of secrecy was conceded it seemed to him that the judge was the proper person to decide: the judge stood between the parties, he represented the community, he knew best the reasons for which the evidence was required, and he was a member of the public and a potential patient and litigant.

DR. MACKEITH was against the disclosure of anything whatever. The secrecy of the doctor should be as absolute as that of the lawyer. When it was stated in the Ministry of Health regulations that the secrets of the venereal clinic would not be disclosed, surely a doctor might be legally, as well as morally, justified in disobeying the order of one of His Majesty's judges. As for concealment of birth, it was not necessary for the carrying out of justice that the doctor should notify birth. The ends of justice were not defeated through the doctor not notifying. As for infectious disease, he maintained that it was the patient's duty, not the doctor's, to notify; let the legal onus be laid upon the patient.

SIR ROBERT ARMSTRONG-JONES said that his sympathies naturally were with medical men in contending for privilege, but he confessed that as a citizen he could not view with approval any immunity conferred upon an individual or a class. Ever since the Reformation it had been the tendency to abolish such privilege. Aristotle laid down the maxim that the State must come before the individual. The true guidance in this matter was one's moral sense, which was decided by the appeal to the intellect and reason, not by authority, or sympathy, or custom. On purely ethical grounds, considering his duty to the State, he found himself unable to support the argument so forcibly brought forward by Lord Dawson.

SIR WILLIAM COLLINS said that he went with Lord Dawson to some extent. The relation between a medical man and

his patient was a very special one. It included a bodily examination, possibly an inquiry into the mental condition, and possibly also something of moral history. The relationship might be so special and so confidential as almost to be akin to that of the priest. In other respects, however, the medical man could not be compared with the priest or with the lawyer. The medical man was a skilled observer of facts as well as a receiver of communications. He could give evidence as to a wound, a scar, a disease, or an abortion. Therefore the question arose as to when it was the duty of the medical man to communicate information. There was no easy formula which fitted the case. He could not agree with the candidate for the martyr's crown (Dr. MacKeith), nor could he adopt the ethical argument of Sir Robert Armstrong-Jones. He had to come down to a lower plane, and to ask whether some measure of privilege ought not to be conceded. The duty of the medical man with regard to communication varied greatly with different cases. Sometimes, as in a case of malignant disease, it was his duty not to communicate the result of his observation to the patient himself, but to communicate it to the patient's friends; at others, as in venereal disease, it was his duty emphatically to communicate it to the patient himself. The relationships of guardian and minor, wife and husband, fiancé and fiancée, involved special considerations. With regard to criminal abortion, he recalled the case of *Kitson v. Playfair*, in which Lord Brampton asked a medical witness whether he conceived it his duty to communicate with the authorities, and on the witness saying that he did Lord Brampton said that he did not take that view at all, and if it were so he would be very careful in his selection of a medical adviser. Lord Brampton seemed to imply that there was a good deal of discretion under the common law. The speaker applauded the late Dr. Elliott of Chester for his resistance to Mr. Justice Horridge, but would have applauded him more had he carried his resistance further.

The President's Summing up.

LORD JUSTICE ATKIN said that anyone who had heard the discussion must be satisfied that this was a very important and living problem, and that there were a number of high-minded professional men who felt acutely the conflict which was raised between their duty as citizens and their professional duty to their patients. There was no doubt that most—he would say all—medical men interested in this question were also keenly alive to the interests of public health. They felt that it might very well be that an unwarranted disclosure of professional secrets might be detrimental to the public health, inasmuch as it would deter patients either from consulting the doctor or, when consulting him, from making that full disclosure which was necessary. This was not in any way an issue between medical men and lawyers, and it was most unfortunate in the interests of the solution which was sought for by the medical profession that it should be put forward in that sense. The lawyer's point of view was solely the administration of justice. The privilege which many years ago was conceded to lawyers, not by statute, but by a development of the common law, probably through the action of judges, was granted because it was considered essential in the interests of justice that clients should communicate perfectly freely with their legal advisers. It was from the same point of view—that of public good—that this other matter must eventually be decided, not by doctors or lawyers, but by the public at large. The question to be decided by the legislature—which, though it contained many lawyers and some doctors, was for the most part composed of patients!—would be whether it was for the public good that privilege should be granted, restricted, or refused. Unrestricted privilege, he believed, was not a practical proposition. At present, in the theory of the law, no privilege at all was granted to the medical man, and in order to alter that position an Act of Parliament would have to be obtained. Therefore any proposals would have to meet with the approval of the legislature, and the last thing that could be obtained from the legislature was an absolute privilege. Absolute privilege meant that if a person was on trial for his life, and on the point of conviction, and a doctor, through information which had come to him professionally, knew that that person was not guilty, but that another person was, that other person being his patient, it would still be the doctor's duty to abstain from giving information. He did not think that even Dr. MacKeith would go as far as that. Even outside the criminal law there were many cases scarcely less crucial. The question often arose in divorce court proceedings. It was

Scotland.

MEDICAL MEN AND ALCOHOL.

THE members of the Glasgow Medical Lunch Club, at the usual weekly meeting on March 23rd, enjoyed an address from Dr. W. L. Reid, who was present as the guest of honour. He chose as his subject the attitude of medical men to alcohol and its place in medical treatment. Dr. Reid has for many years taken a prominent part in discussions on this topic, to the study of which he has devoted much time. His own position was that while he had no belief in alcohol as a beverage or a food, he strongly believed in its efficacy as a medicine under certain circumstances. In view of the widespread abuse of alcohol resulting in crime and disease the general public were more and more looking to the family medical practitioner for advice. Such advice should be carefully considered, as its effects might be far-reaching. The careless prescribing of alcohol had led to the development of the habit in patients. Further, if alcohol is to be given the doctor should naturally choose the purest and most reliable form of the drug, which was that supplied to druggists for medicinal purposes—namely, rectified spirit. His own practice had been that so far as possible alcohol should be prescribed without the knowledge of the patient, and rectified spirit was the most suitable form, as it could be given with something which helped its action and at the same time disguised its taste. He was particularly strong on the bad effects of medicated wines in developing alcoholic habits. These much advertised wines in most cases contained 15 to 20 per cent. of alcohol, and he had known patients who had been advised to use these for tonic purposes develop the habit of their use, while starving themselves of proper nourishing food. Such patients would scorn the idea of becoming addicted to the use of alcohol in the form of whisky or brandy. He finished with a strong appeal to the profession to exercise more care when prescribing alcohol in any form, particularly with regard to its purity and strength and the exact dosage. He agreed with the opinion expressed by a London surgeon that to give alcohol safely required more medical skill than to administer chloroform.

MURRAY'S ROYAL ASYLUM, PERTH.

The report for 1921 by the physician-superintendent, Dr. W. D. Chambers, of the James Murray's Royal Asylum, Perth, states that the number on the registers on March 31st, 1921, was 153, of whom 147 were resident; the total number of cases under treatment during the year was 205. Of the males 47.6 per cent., and of the females 30.7 per cent., entered voluntarily for treatment. Forty-one patients were discharged or transferred to other institutions during the year. Although in only 6 cases was recovery regarded as consolidated, in 17 others so much improvement had taken place that they could suitably be placed under private care. Of the 17 who were discharged as unimproved, 7 were sent to other institutions. In a considerable number of cases mental stress and worry were assigned as the cause of the illness. In very many of these cases it was found, on close examination, that the worry was groundless. It is, Dr. Chambers says, now generally admitted that alcoholic excess, which some years ago was regarded as a cause of insanity, is much more commonly a symptom; the same is, he considers, true of most cases of worry, anxiety, sleeplessness, or overwork; war experience showed that the moderately healthy man can withstand excessive and protracted mental and physical strain without permanent harm. Such conditions may, undoubtedly, produce a state of exhaustion which may lead to a breakdown, but it should be realized that in the great majority these conditions are indications that the danger-point is already passed and that a state of mental disease is already in being. Patients brought under treatment at this stage have an incomparably greater chance of a perfect recovery than those who delay till definite psychotic symptoms develop.

LARBERT INSTITUTION.

At the annual meeting of subscribers of the Royal Scottish National Institution for Mental Deficients at Larbert Dr. R. D. Clarkson, in submitting his report, stated that the number of cases now in the institution numbered over 500, which was as large as could properly be accommodated in the present buildings. The institution was by far the largest

of the kind in Scotland, but it fell short of meeting the need. The directors were distressed to have to refuse to admit many cases because there was no room for them. The waiting list had now 120 names on it, and that would be doubled if the education authorities and parish councils knew that there was any prospect of early admission. The pressure to get children admitted was due to an increased knowledge and a growth of interest among the general public in the subject of mental defect. The Duchess of Atholl moved a resolution that the meeting, while acknowledging the benefits derived by so many through the care and training provided by the institution, recognized the urgent necessity for adequate provision for the mentally defective, and in seeking to extend the benefits of the institution commended it anew to the Scottish people as deserving of their generous support. She went on to say that the institution provided a wonderful variety of occupation for the children, and the inspired intelligence directing the whole work was obvious everywhere. It had been estimated that from 1/2 to 1 per cent. of the child population of Scotland was mentally deficient, and when it was remembered that the age to which the State required mentally deficient children to be cared for was 16 that 1/2 per cent. worked out at 7,000 to 8,000 children, while she understood that the number being treated at special schools or institutions was only between 3,000 and 4,000.

GLASGOW SAMARITAN HOSPITAL.

At the annual meeting of the Glasgow Royal Samaritan Hospital for Women, at which Lady Stirling-Maxwell presided, the secretary, Mrs. Christie, said that during the year 1,755 patients had been treated in the hospital, and 2,130 at the outdoor dispensary. Dr. David Shannon stated that the work of the hospital was increasing every year, and the staff were glad that the hospital was about to be increased in size and twenty beds added. The Samaritan Hospital was one of the biggest hospitals of the kind in the kingdom, and to it came many students and graduates, not only from Scotland but from other countries. Every year the number of these students was becoming greater, and the hospital ought to become a big teaching centre. Mr. Thomas Macquaker, the treasurer of the hospital, said that the sum required to meet all the hospital extensions would be in the neighbourhood of £30,000. Of that sum some £8,000 or £9,000 would be spent on the new dispensary which was now being built, and the rest of the money would be required in connexion with the alteration and reconstruction of the operating theatres, and in adding at least twenty beds to one of the wings of the hospital. The Ladies' Auxiliary Association had given the funds required a good start with £2,400, and the directors had between £4,000 and £5,000 more. They would be able to build the dispensary with the sums they had in hand and in prospect, and he was confident that the remainder necessary would be raised.

GLASGOW ROYAL MATERNITY HOSPITAL.

At the annual meeting of the Glasgow Royal Maternity and Women's Hospital the treasurer remarked on the improvement in the finances of the hospital, the income having increased by £4,500 as compared with the previous year. The net result was that there was a deficit for the year of £3,906, to which had to be added the bank overdraft from the previous year of £13,353. They had been able to meet that from legacies and a special appeal, and were left with a surplus of £2,381, of which £1,026 belonged to the staff fund. They had only been able to get out of their difficulties by making a special appeal, and such appeals could not be multiplied. The Lord Provost said that he could not speak too highly of the work performed by the Maternity Hospital; he was glad to learn that cases dealt with in the hospital were followed up, and that every assistance was rendered to the mothers, by advice or otherwise, in bringing up their children. In 1907, the last year of the old hospital, there were 868 in-patients, but in 1921 there had been 3,625. The number of out-patients, however, was less than in 1907, the reason being the introduction of maternity benefit under the Insurance Act.

EDINBURGH HOSPITAL FOR WOMEN.

The financial difficulties of voluntary hospitals and the medical training of women students were subjects referred to at the annual meeting of the Edinburgh Hospital and Dispensary for Women and Children and the Hospice, held on March 21st. The report stated that last year the hospital

expenditure exceeded the receipts by £1,878. The expenditure of Brentsfield Hospital showed an increase of £4,947 over that for 1913. During the year 571 patients were admitted to the hospital, including 77 children; and 354 confinements were attended from the Hospice. In moving the adoption of the report, commenting on the increase in the number of cases treated in the venereal diseases department, Mrs. Hunter said there was a distinct reaction against women doctors in Scotland at the present time. She was sure the younger women had thought they would not have so much fighting to do to secure their positions. Recently the London Hospital had intimated that no more women students could be admitted. In Glasgow, as far as they could see, there was not the least prospect of any more women getting on the teaching staff of a hospital. The only way was for women to have hospitals of their own. Regarding the remark about the reaction against women doctors in Scotland it might be mentioned that recently there were twenty-five applicants, of whom twenty-three were women, for a vacancy in a provincial hospital for a house-surgeon.

MEMORIAL TO DR. ELSIE INGLIS.

A memorial tablet to the late Dr. Elsie Inglis was unveiled in St. Giles's Cathedral, Edinburgh, on March 21st, by Dr. Mary Scharlieb, C.B.E. The inscription on the lower panel is as follows: "To the beloved and honoured memory of Elsie Maud Inglis, surgeon, philanthropist, founder in 1914 of the Scottish Women's Hospitals for Service with the Allies in France, Serbia, and Russia. Born 1864. Died on active service 1917. *Mors janua vitae.*"

Correspondence.

A NATIONAL COUNCIL FOR MENTAL HYGIENE.

SIR,—There can be little doubt that the subject of mental health, using the term in its widest sense, excites the interest both of the public and of the medical profession more now than it has ever done before. The recent establishment of a few hospitals and clinics for the treatment of "functional nervous disorders," which might be more scientifically labelled "minor disorders of the mind," affords evidence of the fact that the early recognition and treatment of these maladies is generally regarded as a matter of importance in relation to the health of the community. There are, moreover, many societies and associations, old and young, which are engaged in promoting the study of mental disorders, the welfare of the insane, the problems of industrial psychology, and the various aspects of mental deficiency.

A provisional committee of medical men, of which I have been appointed chairman, has decided to form a central organization, a National Council for Mental Hygiene, in order that the work of these institutions and societies shall be encouraged to expand and to add to their usefulness by organized co-operation. Such a National Council for Mental Hygiene will be concerned with other matters which have not yet received sufficient attention. It will help to establish psychological clinics at general hospitals for the treatment of early mental and nervous disorders. It will endeavour to make mental hygiene a more prominent subject in the education of medical students and, by instructing the public in the principles underlying mental health and illness, gradually diminish the enormous waste of time and energy in all classes of society which now results from widespread ignorance concerning these questions.

The conservation of mental health is a matter of serious economic importance to any nation, and this has been fully recognized in other countries, notably in America, where a National Committee for Mental Hygiene has been doing valuable work for a number of years. The chief purposes of that Committee are to work for the conservation of mental health; to promote the study of mental disorders, mental defects, and delinquency in all their forms and relations; to obtain and disseminate reliable data concerning them; and to help to raise the standard of care and treatment; and to co-ordinate existing agencies—federal, State, and local.

These are ambitious schemes; but even a moderate amount of success would spoil happiness and prosperity to many thousands of the population who must otherwise fail in the struggle for existence. Great Britain must not be less ambitious, and must be prepared to join with other nations in an International League, the objects of which will be to spread

the knowledge accumulated by each of its members in all matters of mental hygiene.

The provisional committee consists of: Sir Norman Moore, President of the Royal College of Physicians; Sir Charles Sherrington, President of the Royal Society; Sir John Goodwin, Director-General of the Army Medical Service; Sir George Newman, Principal Medical Officer, Ministry of Health; Sir Walter Fletcher, F.R.S., Secretary of the Medical Research Council; Dr. C. H. Bond, President of the British Medico-Psychological Association; Dr. Bedford Pierce, President of the Section of Psychiatry of the Royal Society of Medicine; Professor George Robertson, President-elect of the British Medico-Psychological Association; Dr. C. S. Myers, F.R.S., Director of the National Institute of Industrial Psychology; Dr. G. Ainsworth; Dr. Helen Boyle; Dr. Edwin Bramwell; Dr. Farquhar Buzzard; Sir Maurice Craig; Lord Dawson of Penn; Sir Bryan Donkin; Dr. Elliot Smith, F.R.S.; Dr. Edwin Goodall; Dr. Henry Head, F.R.S.; Dr. Crichton Miller; Sir Frederick Mott, F.R.S.; Dr. W. H. R. Rivers, F.R.S.; Sir Humphry Rolleston; Dr. T. A. Ross; Dr. Tredgold; Dr. W. Worth.

This committee will call a general meeting on May 4th, 1922, at the rooms of the Royal Society of Medicine, for the purpose of deciding on the constitution of the National Council, of electing officers, and other business. Meanwhile the honorary secretary will be glad to receive the names of all persons, lay or medical, who are interested in this movement and who would care to have more particulars sent to them. Communications should be addressed to the Honorary Secretary, National Council for Mental Hygiene, 51, Green Street, W.I.—I am, etc.,

COURTAULD THOMSON.

March 27th.

REDUCTION OF MEDICAL FEES.

SIR,—At the time that the cost of living was at high-water mark or thereabouts I think I am right in saying that the Council of the British Medical Association recommended the profession to increase their fees by 50 per cent., and this, I believe, was generally done. Considering the financial crisis the country is now passing through and the reduced incomes of our patients, together with the somewhat reduced cost of living, I would like to suggest that the Council should again consider the advisability of recommending now a reduction of that 50 per cent. increase by, say, 20 or 25 per cent.

It is a well-known fact that throughout the country there is a feeling, owing to various causes, of antagonism to the profession, and I am convinced that no greater move to reduce that antagonism could be adopted than a spontaneous and voluntary reduction of the increase of fees which was adopted when the cost of living was so high and which was then quite justifiable.—I am, etc.,

Woldingham, Surrey, March 21st.

W. McD. ELLIS, M.D.

RESTRICTION OF INFLUENZA EPIDEMICS IN SCHOOLS.

SIR,—Influenza in a school is so serious a matter that I turned with interest to the article in your issue of March 18th by Dr. A. I. Simcy and Dr. J. W. H. Eyre, entitled: "The restriction of influenza epidemics in schools by the use of local prophylactic vaccines." What Rugby does is of some importance, and, if I may say so, what Professor Eyre writes is of some importance. Yet I do not remember to have encountered figures in any published work which were more at variance with the conclusions drawn from them.

Three separate attempts were made by vaccination to avoid or mitigate the epidemic. A request was issued that boys should be vaccinated in the holidays. Of 570 boarders 123 complied. The remainder came back "uninoculated and susceptible." Although the authors do not analyse their figures from this point of view, it is clear from other statements that of those vaccinated at home 42 per cent. suffered, of those not vaccinated at home 43 per cent., despite the fact that many of these later received vaccination at school.

In the third week of the epidemic a stock vaccine was given at school to nearly all those who had not been vaccinated at home or who had not already sickened. Fifty boys received only the stock vaccine; 84 per cent. were infected.

Apparently the home inoculation was without result, and the stock vaccine according to the authors doubled the risk. A third vaccine was administered to an unspecified number of

boys. This autogenous vaccine was given in the fifth week of the epidemic, when the incidence was rapidly declining and when approximately four-fifths of the whole epidemic was over. Although no figures are given to support the contention, and the total number of boys who received the vaccine is not even mentioned, it is to be presumed, in view of the demonstrable failure of the other two attempts, that it is for this autogenous vaccine that success is claimed. We are told that 81 per cent. of those who received no inoculation were infected, of those who received one or more inoculations 27.9 per cent. Will it be believed that to produce these figures the total under the head of unvaccinated is swelled by all those who contracted the disease during the height of the epidemic before the school inoculations began? The autogenous vaccine was given too late for conclusions of any value to be drawn. Why, if the authors had waited another week or two, on this plan of reckoning, a point might be reached when the unvaccinated—that is, all those who had had the disease—would show 100 per cent. incidence, the inoculated complete immunity. The vaccine was given, not at the conclusion of the epidemic, but after approximately four-fifths of it was over.

It is a pity that the figures should have been presented in the way they are, because Dr. Simey and Professor Eyre must have the facts in a form which, had they been properly presented, would have enabled some conclusion to be drawn. Thus for the first fortnight the effect of the home vaccine might be demonstrated by comparing the percentage of cases among those who had received it and those who had not. Apparently in the third week of term all or nearly all received the stock vaccine, so that no controls were available. In the case of the autogenous vaccine, however, a proportion may not have been inoculated. The only figures of value would be the incidence after the fifth week in those who had received the autogenous vaccine and those who had not, and to the total who sickened among the unvaccinated there should not be added the relatively vast number who had contracted the disease before inoculation was carried out.

But it must be conceded that the authors are strictly consistent. When their peculiar methods of statistical inquiry tell against them they do not quail. Thus they regard the effect of the stock vaccine as raising the case incidence to the appalling height of 84 per cent. Of course it did nothing of the sort. A number of boys, apparently about 300, were given the stock vaccine. In the next fortnight 42 of these sickened. At this point all but 8 of the remainder were given a second autogenous vaccine and are thereupon removed by the authors from the category of the unvaccinated. Since 42+8 received only the stock vaccine and 42 had influenza, the incidence, they say, was 84 per cent. This, we are gravely assured, "represents the well-known fact that susceptibility to infection is temporarily increased by the first of two such inoculations." It represents nothing of the sort. If all who had not already sickened, instead of all but 8, had been given the second vaccine the incidence among those who received the first stock vaccine only would have been 100 per cent.

I write at length because I fear that the figures given, or rather the quite unwarranted deductions from them, may become known to schoolmasters and others. In a few years' time they may even be quoted with confidence as "The Rugby Statistics" showing an 81 per cent. incidence among the unvaccinated.—I am, etc.,

London, March 23rd.

H. CHARLES CAMERON.

SIR.—In their article on the restriction of influenza epidemics by the use of "local" prophylactic vaccines (BRITISH MEDICAL JOURNAL, March 18th) Drs. A. I. Simey and J. W. H. Eyre describe their efforts to prevent and control an epidemic of influenza at Rugby School. Although they do not state definite conclusions, it is obvious that they consider that the vaccines they used were of prophylactic value.

To my mind, however, their evidence is wholly inconclusive. The curves represent the number of cases under treatment, but a single curve showing the daily incidence of new cases would be of greater value, for it would exclude the influence of the duration of illness, as foreign to the present investigation.

An examination of a curve obtained by combining the two given shows that the average daily increase or de-

crease in the number of cases under treatment was approximately:

	Increase.		Decrease.
First week 2	Fifth week 10
Second week 7	Sixth week 4
Third week 12	Seventh week 2
Fourth week 1		

The daily rate of increase in the number of patients under treatment was at its greatest (21) on February 3rd (that is, the curve was then at its steepest). This was the date of the first inoculation. But the maximum daily increase in the incidence rate must have been several days earlier, so that the first inoculation was given after the incidence curve had begun to lose its steepness.

The number of patients under treatment reached its maximum on February 12th (in the middle of the fourth week of the epidemic). During the fifth week the number of patients was falling rapidly (ten a day). The incidence rate must have been falling some days earlier. It was during this week that the second (local) vaccine was given.

We may therefore conclude that the first inoculation was given when the curve of incidence had passed its steepest inclination, and that the second inoculation was given when the disease was already declining rapidly.

Compared with that of an ordinary epidemic, the curve does not appear to be appreciably modified by the inoculations. With regard to the statistics:

1. Of the 123 boys comprised in Class (b) (boys inoculated at home) 52 became infected—a case incidence of 42 per cent. Of the 442 boys who were not inoculated at home 191 contracted influenza—an incidence of 43 per cent. The home inoculations, therefore, had no significant effect.

2. Why did not the boys of Class (d) receive a second (local) dose? Obviously, in nearly every case, because they contracted influenza during the intervening period. The 84 per cent. incidence is misleading. In all, 282 received the first dose, of whom 61 became infected (incidence 22 per cent.), most of them while the disease was at its height. There is here no evidence that susceptibility is temporarily increased by inoculation.

3. Class (a) had resisted the epidemic, now on the decline, for four and a half weeks, when the second inoculation was given. They were picked cases, and the disease was dying a natural death. In general I can find no evidence that any of the inoculations affected the course of the epidemic.

The only (conjectural) positive inference to be extracted from the chart is that the sanatorium of Rugby School normally contains about 45 beds, capable of increase to 72 in emergency.—I am, etc.,

Chingford, March 19th.

E. BILLING, M.R.C.S.

PROSTATIC ENLARGEMENT.

SIR.—The Hunterian lecture by Professor Kenneth Walker is of very great interest. The possibility of a relationship between enlargement of the prostate and some change in the endocrine system, so ably put forward by him, is at present surely too problematic to form the basis of treatment by organotherapy, and especially since it is extremely difficult in these cases to estimate the reaction to treatment.

The enlargement of the prostate may remain latent for years, and the first sign may be a sudden attack of retention, which may be followed by acute renal failure. When once symptoms have appeared they are generally progressive, but periods of improvement and intermission are common apart from any treatment. Our present method of estimating the degree of enlargement—namely, by cystoscopic and rectal examination—is not sufficiently accurate to allow of the expression of a definite opinion on its progress. In addition it seems that the enlargement may vary in size from time to time, and this, I think, is dependent upon the amount of congestion and possibly upon some relation to the sexual cycle. In the circumstances it is by no means easy to know whether an improvement can be attributed to treatment.

The value of treatment cannot be gauged merely from the relief of symptoms, important as this may be, for its effect upon other conditions resulting from enlargement of the prostate must also be considered, the chief being the tendency to malignant degeneration and the secondary renal changes. That the enlarged prostate does show a predisposition to undergo malignant changes is evident from the examination of specimens removed at operation and also from the course of some of the cases. Cases where an apparently simple adenoma of the prostate becomes inoperable at a later date

owing to malignant changes are only too frequently seen. At the time that the enlarged prostate is revealed by symptoms, I am led to believe from investigations carried out that secondary renal changes are already present. These progress insidiously, and uræmia is the usual termination of the enlarged prostate; it is also responsible for a large percentage of the operative mortality.

I have occasionally used prostatic extract in early cases and when operation has been refused, but with no definite benefit. Such treatment does not appear to be based on sound physiological principles. It is doubtful if the prostate forms an internal secretion, for in cases where it is largely destroyed by tuberculosis or suppuration no symptoms or signs which could be related to the disappearance of an internal secretion are to be found. Were the enlargement secondary to some physiological need, its removal should be followed by some disorder of function. Yet the man who has undergone prostatectomy is sound in body and mind. The mental changes sometimes seen are uræmic in nature. At one time I gave after operation a mixture of the glandular extracts upon the assumption that the endocrine glands suffered in the toxæmia resulting from the renal changes. It had apparently no result, and was discontinued as the action of some of the constituents was to raise the blood pressure, a condition it is most desirable to avoid. Prostatic extract had no effect. Renal extract may be of value, but so far it has not had an extended trial.

In recent years there has been a marked improvement in the operative statistics, due partly to improved technique but largely to the fact that it has been realized that palliative measures have only a temporary action and are in the long run harmful, and consequently the operation has been performed before renal changes have become advanced. A course of organotherapy might be tried in early cases, but not when once operation is indicated, unless this is refused. The results should be carefully scrutinized, since it is almost impossible to foretell what the clinical course of any case would otherwise be.

During the last two years I have seen a number of men between 45 and 55 years of age, complaining of some perineal discomfort and occasional nocturnal frequency. The prostate appeared to be larger than is normal at this age, but no evidence of inflammatory changes was to be found. The condition cleared up after local treatment and attention to the mode of living. One would, however, hesitate to claim that these were cases of incipient enlargement of the prostate. —I am etc.,

Cardiff, March 24th.

T. E. HAMMOND.

THE RECOGNITION OF AORTIC INCOMPETENCE.

SIR,—I should like to reply briefly to Dr. Rudolf's interesting comments on my paper on aortic incompetence. In none of my cases it is stated that the diastolic murmur was ever inaudible by me; it was always heard. All of the cases had enlargement of the heart, and this was downwards as well as outwards. In four of them enlargement downwards probably reached to behind the sixth rib; it did not reach the sixth intercostal space. It is these slight enlargements of the left ventricle that are such an important pointer to diagnosis of aortic disease. The apex is noted as being in the sixth space in one of the cases, and in the two which died it was there also, though I have omitted to say so specifically. All the cases were undoubtedly of aortic origin, as I am sure Dr. Rudolf would have said had he seen them.

The pulmonary diastolic murmur which is heard in advanced mitral stenosis—called by Dr. Steell the murmur of high pressure in the pulmonary artery—is a different matter altogether, which I will not go into here. I may, however, thank Dr. Rudolf for the reference to his and other observers' work on the matter.

I am sorry that I cannot hear ear to ear with Dr. Broomhead, and in reply to his last communication will merely say that I do not know the systolic murmur which he finds is quite common in the second right space in healthy persons.—I am, etc.,

B. M. BROCKBANK.

Manchester, March 23rd.

THE ETIOLOGY OF RHEUMATIC FEVER.*

SIR,—It was shown by Sir Arthur Newsholme in the Milroy lectures of 1895 that rheumatic fever bore a relation to the level of the ground water, and followed, in the late autumn and early winter (even in epidemic proportions), a hot, dry summer. In those lectures he did not suggest why the

* In order to save space it has been necessary to omit some passages of this communication.

disease should have this relationship with meteorological conditions; he merely stated facts.

In a previous paper¹ I have shown that rheumatic fever does not occur in the Malay Peninsula, and probably not in the tropics at or about sea-level; and later on I tried to present a case for believing that the common rat-flea of temperate climates, *Ceratophyllus fasciatus*, is the cause of the disease.² The fact that the disease and the flea have similar affinities, that both occur in one part of the world and not in another, and the fact that those meteorological conditions which Sir Arthur Newsholme showed to cause an increase in the amount of rheumatic fever are those under which the rat-flea thrives best, point to a connexion between the flea and the disease.

Out of 97,914 deaths recorded in the State of Perak during five consecutive years not one was ascribed to rheumatic fever; in one year 103,609 in-patients were admitted to the hospitals of the Federated Malay States, but not one was diagnosed as suffering from this disease. Further, no case of mitral stenosis has been recorded in any of the returns of the Government hospitals or pathological institutions of the Malay Peninsula. These figures may be compared with the 2,000 cases of rheumatic fever per million living in Scandinavia,³ and with the 6 cases of rheumatic fever out of every 45 adults occupying hospital beds in London.⁴

The non-existence of mitral stenosis in the tropics is most significant. A rheumatic lesion of a valve is characterized by a "slowly advancing scar formation"; "it is an associated condition of fibrosis and vascularization."⁵ It is not the contraction of a scar already formed. The continuity of the process would seem to indicate that the cause is continuous; if an infection, a continuous infection. But in the latter stages bacteria cannot be found except as grafts. It seems probable that the cause of a disease, when a continuous process is going on and bacteria cannot be found, may be a protozoan. Two other diseases in their later stages show a slowly advancing scar formation: syphilis, which is a cause of many cirrhoses, and malaria, in which chronic enlargements of the spleen and liver show much increase of fibrous tissue. These lesions are bacteria-free, but both syphilis and malaria are caused by a protozoan.

An insect may either carry a bacterium or may be the host of a protozoan. I am suggesting that *Ceratophyllus fasciatus* is the host of a protozoan which is the cause of rheumatic fever, man and the rat being the alternative hosts.

A few cases of rheumatic fever have been said to have occurred in the tropics. But much has to be eliminated, especially diseases occurring in malarial subjects, before the diagnosis can be accepted. I submit that no case should be accepted until the complete syndrome of a typical case is present. A claim that an atypical case proves the presence of a disease cannot be conclusive. Neither rheumatic fever nor the flea, *C. fasciatus*, exists in the tropics.

At no part of any year—hot or cold, wet or dry—are the conditions in England similar to those of the tropics. In England a temperature of 76° F. perhaps never occurs, except for a few hours at a time; the mean of the tropics is 80° F. or a little higher. The climatic conditions of the late autumn and early winter of England obviously cannot occur in the tropics.

Dr. Jordan,⁶ of the Tring Museum, has investigated the distribution of *C. fasciatus*. This he gives as from the Azores to Asia Minor, from Cyprus and Italy northward to Scotland and North Russia, extending (probably over Siberia) to Japan. Only one specimen has been found in the tropics, and this was in Bombay, and may have been imported. One other specimen was found in India at Bareilly, but this place is not in the tropics. *C. fasciatus* may exist in India, but not in the tropical part, which includes only about one-third of the peninsula. Other *Ceratophyllus* have been found in India, but these species, such as those of squirrels, have but few opportunities of biting man. Further, a difference of species is quite sufficient to determine different carrying powers in a given genus—a fact clearly shown by the different capacity of the various anophelines in carrying malaria.

Study of the bionomics of the rat-flea has shown⁷:

1. That the insect can stand temperatures up to about 76° F. (higher for short periods), and that at high temperatures it lays more eggs, and that a higher percentage of these are fertilized.
2. That a high temperature is best for the hatching of the eggs.
3. That the larvae do best at a temperature of about 61° F., with a high relative humidity, but they are killed instantly by getting wet.
4. That the cocoons lag under the heat of summer and the cold of winter, the insects emerging most frequently under the conditions of spring and autumn.
5. That the maximum incidence of this flea is in the early autumn.⁸

Thus it will be seen that the larval state, the most dangerous in the life of the flea, is least likely to be interfered with when the ground water is low, and further that a hot, dry year is the most favourable to every stage in the life of the flea. It will be seen that the normal highest incidence of fleas precedes by but a few weeks the rise in the incidence of rheumatic fever.

Sir Arthur Newsholme mentioned that rheumatic fever is more common in those counties which have a large urban population. In Cambridgeshire by far the largest number of fleas collected from rats were *Ctenophthalmus agyrtus*.³ This flea is a country flea and is said not to bite man. *C. fasciatus* is a town flea and does bite man.

Finally, I may say that as the geographical distribution of subinfective endocarditis, rheumatoid arthritis, and of scarlet fever are similar to that of rheumatic fever, the cause of these diseases must be searched for along the same lines as that of rheumatic fever. They are possibly all caused by protozoa and possibly all flea-carried. If this is so, it may be that a cure will be found in some such drug as is successful in the treatment of other protozoal diseases.—I am, etc.,

PERNICIOUS ANAEMIA AND SEPTIC ANAEMIA.

SIR,—In Dr. Hunter's lecture (March 18th, p. 421) there is one statement which appears to be due to a misinterpretation of the appearances of the bone marrow. He says:

"Furthermore, the action of septic infection is to retard blood formation in the bone marrow (a pale bone marrow). It thus counteracts the action of the haemolytic infection, which is to stimulate blood formation (red bone marrow). The removal of the sepsis therefore frees the bone marrow from a markedly depressing influence, and allows the full compensatory powers of the bone marrow free play."

If Dr. Hunter be correct in his belief that there is a separate septic element in the so-called pernicious anaemia, one would be glad to know why the pale bone marrow should be one which is in a state of depression rather than one in a state of leucoplastic reaction. One cannot regard the presence of a septic infection as an influence likely to depress the haematopoietic functions of the marrow; it is rather one which leads to an increased function. The pallor of the marrow may thus be due to an increase of marrow activity in the direction of leucopoiesis, but it must be remembered that the precursors of the red corpuscles are colourless and that, therefore, a marrow in which much early erythropoietic activity is occurring would necessarily be pale.

Another important point which requires elucidation is the line of separation between septic anaemia and haemolytic anaemia: the degree of haemolysis in septic infections as observed at autopsy can be gauged by the intensity of the "free iron" reaction in the liver, and if Dr. Hunter will try this reaction in a number of cases he will find that it is positive in all cases of some standing.—I am, etc.,

Birmingham, March 18th.

ALFRED PINNEY, M.R.C.P.Lond.

GOITRE.

SIR,—Without being able to add any experience of mine as to the correctness of Dr. Martin's "analogical guesswork" (March 11th, p. 412) in his treatment of enlarged prostate, I can confirm his experience of the success in the "patient administration of small doses of thyroid extract in cases of early soft parenchymatous goitre." Dr. Martin, however, is only partly correct in his statement that "it is no good giving thyroid extract in cases of enlarged thyroid of long standing." I have recently treated such a case in a woman of 45 whose gland became suddenly painful with increased enlargement, particularly on the right side. The pain ceased and the gland decreased in size after a few weeks of thyroid extract. The patient believes that the whole gland is less than it was before the acute symptoms commenced, but of this I am not able to judge, though I have seen improvement in other long-standing cases under the same treatment, but never cure as in the soft variety of goitre. In Dr. Rudolf's able and interesting paper on "The treatment of insomnia" no mention

is made of the part a loss of balance of the endocrine secretions may play in the cause of sleeplessness. Some two years ago I treated a woman of 50, of whose family four have suffered from goitre, but who has never had goitre herself. She complained of debility, exhaustion, and particularly of sleeplessness. Remembering her family history, that her two younger sisters had goitre, and that I had cured her two daughters (aged 12 and 15 respectively) of this trouble, and as the ordinary remedies for insomnia had failed to give relief, I resolved to try thyroid extract. The effect was almost immediate, as she began to sleep soundly after a few doses and so far has remained cured of her insomnia. Such a result, of course, may have been merely *post hoc*, but if *propter hoc* it is a considerable support of Dr. Martin's system of "analogical guesswork."

In Dr. Gibson's interesting statistics on goitre he might have added Warrington to his list, for the number of Warrington patients who come for other troubles, but who unsuspectingly have more or less enlargement of the thyroid gland, is truly astonishing. The water in Warrington is unusually hard, which also may account for a good deal of the rheumatism prevalent there. Yet neither defective water nor fats are alone responsible for goitre. Excess of chocolate is just as bad, and also of oranges and lemons, and so is excess of bread. I know a girl of 18 whose only error in diet is that she will eat as much bread at one meal as would suffice three average adults. The detriment in her case is a steadily developing goitre; otherwise it is reasonable to suppose that she would put on fat or suffer from rheumatism, or some other trouble arising from toxæmia, and if so, her enlarged gland is a clinical picture as to the reason of the efficacy of thyroid extract in obesity and ailments arising from the rheumatic diathesis. The starch in the bread becoming sugar in the system acts like the chocolates in overloading the organism with urates. The acids in oranges and lemons probably act much as the fats do in producing goitre. To eat these things in excess so long as the excretory systems remain intact will do little harm; but the trouble is that in most cases the kidney eliminative cells, chiefly the tubular epithelia, are rendered half dormant by the toxins induced by such excess in diet. Hence the demand for increased thyroid secretion, possibly to correct the defect in the kidneys, and hypertrophy of the gland in consequence.—I am, etc.,

Liverpool, March 12th.

WILLIAM BRAMWELL.

THERAPEUTIC EFFECT OF IPECACUANHA IN COMBINATION WITH TANNIC ACID.

SIR,—Your report of the Tropical Diseases Section of the Royal Society of Medicine (December 31st, 1921, p. 1115), I regret to say, has incorrectly stated that I "confirmed the benefit derived from the combined use of tannic acid with emetine or ipecacuanha," by Dr. Mansou-Bahr and Sir Leonard Rogers.

My statement was that I could corroborate the fact that *neither nausea nor vomiting was caused by doses of 20 or 30 grains of ipecacuanha if combined with tannin*. I had given some hundreds of such doses in the years 1916-17, and had found *no clinical benefit therefrom* before I recollected that tannin was an antidote to most alkaloids. I found that emetine was precipitated by tannin and that when adding tannin to ipecacuanha we were practically giving *ipecacuanha sine emetina*, or, in other words, *ipecacuanha sine bono*.

Ipecacuanha is usually given on an empty stomach. Vomiting after the ipecacuanha alkaloids or their salts does not as a rule take place till one or two hours after being swallowed. From this we may conclude that it is absorbed from the intestine. If the tannate be dissolved by the HCl of the stomach it is promptly precipitated again on reaching the intestine.

In confirmation of Professor Dudgeon's opinion that past histories of dysentery were often open to doubt and unreliable, I stated that I had performed autopsies on six cases who had died of liver abscess who said they had never suffered from dysentery, and in all six I found either active ulceration or scarring in the colon.

Since the meeting I have asked Dr. G. Roche Lynch to repeat my former tests, which he was kind enough to do. His report states:

"(1) If tannic acid in solution is mixed with emetine HCl the faintest opalescence is obtained.

"(2) If tannic acid in solution is added to a solution of emetine (base) a distinct opalescence is produced.

"(3) If to the opalescence obtained in (2) a drop of HCl about 0.1 per cent. is added the precipitate immediately disappears.

"(4) If to a mixture of emetine HCl and tannic acid or emetine base and tannic acid a minute fragment of NaHCO_3 or a drop of very diluted solution of NaHCO_3 is added an immediate heavy precipitate is obtained.

"The experiments show that in the stomach emetine in the presence of tannic acid is in solution, but that as soon as the stomach contents reach the small intestine (the contents being alkaline) the emetine is precipitated in the form of tannate, which is consequently not absorbed. I suggest this as an explanation of the absence of the vomiting when ipecacuanha is given with tannic acid.

"The vomiting, I am informed by Dr. Powell, occurs about two hours after taking, which is suggestive that the ipecacuanha alkaloids are absorbed mainly from the small intestine and only slightly, if at all, from the stomach.

(Signed) "G. ROCHE LANCHE.

London, W., March 16th.

ARTHUR POWELL.

THE NAVAL MEDICAL SERVICE.

SIR,—The letter of Mr. Gerald Sichel (February 18th, p. 292) caused me to refer to a report by the British Medical Association on "The shortage of medical officers in the Royal Navy," which was published in the *JOURNAL* of July 11th, 1914, with a view to ascertaining how many of the reforms therein suggested have been carried out in the eight years that have elapsed. The suggestions were under seventeen headings. Of these it may be claimed that only six have been fully or partially adopted, while the remaining eleven are still amongst the grievances of to-day, so it should not be a matter for surprise that there is still some discontent in the Naval Medical Service, or that as a service it is unpopular outside.

Since the report referred to the titles of the medical branch have been brought into line with the deck or executive branch, and the "curl" has been added to the pre-existing medical branch distinction mark, but this "reform" was somewhat half-hearted, and it must not be imagined that a medical officer in the navy has the privileges of an officer of similar seniority in the executive branch. For instance, he cannot yet be president of the mess in which he is the senior officer; he cannot sit on courts martial even when one of his own branch is being tried; he does not get a cabin commensurate with his seniority; and he is at a disadvantage in the matter of boats. While the medical officer is thus debarred from many of the privileges which should have accompanied the changes of titles, he does not escape the disabilities; and if he be put on half-pay, or retire on a half-pay basis, he draws the half-pay of his executive, not medical, rank.

Medical specialization has been introduced since the report, but in a way which has produced some discontent rather than the reverse, for officers are appointed as specialists without any previous training or examination, so that the only way in which an officer who desires to specialize can do so is to beg for an appointment as such. Hospital appointments, too, are made in a haphazard manner in the first instance, and perhaps there is no great difference in the medical attainments of naval medical officers on joining; but the matter is one of some importance to the individual, since the appointment to a hospital introduces the officer into a sort of "inner circle," which ensures his return to hospital at some future time and enhances his chance of promotion.

Another grievance is the reduction of the retiring age for surgeon commanders from 55 to 50, which has the effect of depriving a large number of senior officers of five years of full pay at a time when their families are growing up and when they themselves are well capable of continuing their work.

When discussing naval pay one should not be misled by any comparison of the "daily rate" of the various branches, for it must be remembered that the executive branch alone are entitled to such allowances as command pay, table allowance, entertainment allowance, etc., many of which are free of income tax, and may amount to over £1,000 per annum in the higher ranks.

There are two schemes by which the disabilities of the Naval Medical Service can be removed:

1. To grant to medical officers all the privileges of their relative rank with the executive branch, while retaining their pay on a higher relative scale by a "professional allowance," as obtains at present.
2. To combine all the military medical services of the Navy, Army, and Air Force, thus making a British medical service.—I am, etc.,

SURGEON COMMANDER.

SUICIDE IN BORDERLAND CASES.

SIR,—In reply to Dr. Plummer's interesting letter (p. 371), I would like to say I entirely agree that the care given to cases of mental disorder should be assimilated to the kind of care we bestow upon bodily disorder (a view shared by a Commissioner, Dr. C. Hubert Bond). This would seem the only method by which the foolish idea of taint or stigma can be swept away.

Dr. Plummer asks, "What does Dr. White want?" I want the methods in vogue under the present lunacy system to be revolutionized. A medical superintendent once said to me, "If I thought I was going to be put in a lunatic asylum, I would shoot myself!" Until hope and cheer are substituted for suppression, reassurance for intolerable anxiety, interest and occupation for vacancy, comprehension and kindly sympathy for indignity, asylums will continue to be dreaded worse than death; and the very thought of being "put away" will not cease to be a fruitful cause of attempted suicide. It seems in the last degree irrational to subject depressed cases to an atmosphere of dismay, ignominy, foreboding, and acute distress. I know of a few asylums where the atmosphere is the opposite of that just described, where the head-doctor is beloved, and where patients are not afraid to apply for readmission. Let us hope that within a few years such mental hospitals, in the true sense, will become the rule.

Meanwhile the need of the uncertifiable is for sanatoriums run on purely hospital lines—that is, without detention, and having no link with lunacy—to prevent early cases becoming certifiable. Professor G. Robertson has assured us there is nothing to prevent these being started immediately, and the benefit from them would be incalculable.

I have always favoured the proper procedure of legal certification for the certifiable, with provision for full inquiry and right of appeal. A man should be tried for his sanity as for his life, and no safeguard provided by the Lunacy Act should be infringed. The "alleged lunatic" ought to be told of the allegations made, and have the benefit (should he desire it) of legal aid. I am opposed to every attempt made in recent years to place any patient under lunacy control by some subterranean device intended to evade judicial certification. Liberty is too precious a thing to be thus jeopardized.

The Board of Control is to blame, I think, for ratifying without careful inquiry every (amended) certificate sent up to them, when scrutiny would have detected instances where the requirements of the Lunacy Act had been ignored, or where the grounds for committal are patently frivolous. The Board is to blame also for not invalidating certification when conspicuous illegalities are brought to their notice by a patient who has only been able to discover them upon discharge—for example, where he has not been accorded his right of appeal to a magistrate, or where his own doctor's opinion has been put out of court (as in a recent case), "for the reason that two mental specialists had already been called in." Such negligence is likely to bring the proper function of the Board into disrepute.

The problem of dealing properly with the certified would be immensely simplified if asylums were cleared of all inebriate, puerperal, epileptic, and mental deficiency cases, and if these classes were relegated to appropriate homes. Infirmarys ought to be obliged to retain and deal with their own transiently delirious cases, instead of being permitted to dispatch them to asylums, to their detriment. The medical and nursing staffs of asylums would, after this clearance had been effected, have a much better chance of promoting the recovery and restoration of the really insane.

Lastly, I desire to thank "M.D." for his friendly reminder about the Board of Control in your issue of March 11th, but would like to explain my reason for the name I used. The Board is composed of Lunacy Commissioners *plus* Mental Deficiency Commissioners. I have been dealing solely with the former, and the Lunacy Act differs in its provisions from the Mental Deficiency Act. No one would rejoice more than I at the sweeping away of any opprobrium connected with mental cases.—I am, etc.,

S. E. WHITE, M.B., B.Sc.

London, March 13th.

CHEAPER SPAS.

SIR,—By its recent decision to reduce existing charges the British Spa Federation has shown some courage, but I think wise foresight. For though it is at present admittedly difficult for spa establishments to be self-supporting, yet it is equally true that they cannot really and permanently

flourish unless they are made available for all sections of the population.

The remarkable curative results obtained at the mineral waters hospitals in our country, as well as their long waiting lists and the financial support given to these institutions by those who profit by them, show not only the solid medical work done at the British spas, but the appreciation in which this work is held in the industrial world, both by employers and employed. Unfortunately, as elsewhere, the private patient often fares less well than the hospital patient, and yet it is hard to see why the benefits enjoyed by the rich and by the poor should not be made available for persons of straitened means.

I venture to assert from long experience that many delicate people, as well as invalids, ought to take their annual holiday at one or other of the spas, at home or abroad. The complete change, the mental and physical rest, the fine air, and pleasant recreations, make an ideal background for the skilful use of waters and baths, and experience continually shows that chronic ailments are best held in check by such means and valuable lives prolonged for many years. How can such benefits be brought within the compass of hard workers with reduced income? They cannot afford the best hotels. I have often thought that the need of these serious visitors would best be met by clean and wholesome "spa hostels" or "spa pensions" providing a simple and regulated diet. Something is wrong if, broadly speaking, the spas can only cater for the "rich" and the "poor."

Another serious matter for the British spas and their clientele is the increased cost and diminished facility of the railway service. Many years ago the railway companies concerned consented to run through carriages from London to a spa in the Highlands during the summer months. The return fare was then sixty-three shillings. By this means not only were invalids and ladies travelling alone able to make the journey in safety and comfort, but also thousands of jaded and ailing health seekers. Now it is cheaper to visit a French or Swiss spa than to make this journey to Scotland. I hope that, in view of such facts, every support will be given to the British Spa Federation in their efforts to secure a better railway service.—I am, etc.,

London, W., March 22nd.

R. FORTESCUE FOX.

GERMAN-MADE SURGICAL INSTRUMENTS.

SIR,—Letters have recently appeared (BRITISH MEDICAL JOURNAL, February 25th, p. 331, and March 18th, p. 457) with regard to the importation of German x-ray and electro-medical apparatus, and we should like to draw the attention of the medical profession to the fact that the same conditions apply to the surgical instrument industry.

The training of the highly skilled workmen in this trade involves an apprenticeship of six or seven years, and the remuneration has never been high as compared with less highly skilled work. The making of surgical instruments is really a handicraft, and does not lend itself to "mass production." In following the progress of modern surgery new models are being constantly evolved and the older ones discarded. The variety of the work is phenomenal, as may be seen by reference to any instrument maker's catalogue.

At the present time there is much "short time" and unemployment among a most deserving set of men, due in great measure to the importation of German instruments, which, owing to the difference in exchange, are being offered at or below pre-war prices. It should be noted that such instruments are not equal to the high standard of British manufactures.—I am, etc.,

G. R. CHEESMAN,

Hon. Sec. Surgical Instrument Manufacturers' Association (Incorporated).

March 21th.

THE CONFERENCE OF STAFFS OF HOSPITALS.

SIR,—At the Conference of Hospital Staffs in December, 1920, the Chairman of the Hospitals Committee, in opposing the admittedly logical arguments of Dr. Peter Macdonald, pleaded in eloquent terms for the retention of the voluntary system on sentimental grounds, saying that unlogical people and things might yet be very lovable. Such was the moving force of this appeal that the amendment of Dr. Macdonald was lost by an immense majority. In the afternoon the delegates, refreshed doubtless by an interval for lunch, took a more robust and worldly view of the situation, and urged thereto by the quite unsentimental but, as he truly claimed,

strictly logical arguments of the Leicester representative, agreed, also by a huge majority, to get all the money that they could. Now, at the recent conference, the staff delegates, while adopting various proposals calculated to increase very materially the labour of lay administrators, endorsed the unfamiliar doctrine that the essence of the voluntary system is that these gentlemen alone should work unpaid. In plain English, they are to be told to put their backs into it, and labour overtime without remuneration of any kind, in order that the "honorary" medical staff may be paid for practically all that they do. Having, I confess, some diffidence in placing this view of their duties before our lay board, I should be indeed grateful if the Chairman of the Hospitals Committee, or other leading light, will advise me whether this particular proposition is to be advocated entirely on the plea of sentiment, or is, on the contrary, to be recommended on the score of logic. Also I am tempted to wonder how long these often busy laymen who, unlike the medical staff, reap no indirect reward, will continue to officiate under these somewhat novel conditions, and what will happen to the voluntary system when they revolt.—I am, etc.,

Chichester, March 21th.

G. C. GARRATT.

"A CENTURY OF MEDICINE AT PADUA."

SIR,—Sir George Newman's essay, reviewed in your columns to day, is addressed to the students of St. Bartholomew's Hospital and is the outcome of the musings of its author "on a sunny spring morning in the year of our Lord, 1921."

The pamphlet is *undated*; but I think it must have been published since my Harveian oration (October 18th, 1921). Owing to the absence of the date on Sir George Newman's publication and the incorporation in the essay of some sentences closely resembling those in my Harveian oration (to which no reference is made) it might be thought that I had copied them from Sir George Newman's essay, which is not the case. Of the University building at Padua I wrote: "From contemporary prints we can see what the University building—the 'Gymnasium omnium disciplinarum'—was like. . . . Over the gateway was the stemma of a Doge of Venice and beneath it the Lion of St. Mark. . . . There still remains the legend 'sic ingredere ut te ipso quotidie doctor evadas.'" Sir George Newman writes: "Over the gateway was the Lion of St. Mark with the legend *Gymnasium omnium disciplinarum*, and above the escutcheon of the Doge of Venice the words 'sic ingrede [sic] ut te ipso quotidie doctor evadas.'" I was at some trouble to ascertain the significance of the "Cicogna" stemma over the gateway, as indicated in a footnote (BRITISH MEDICAL JOURNAL, loc. cit.).

Sir George Newman's essay contains some misspellings of proper names—for example, "Aldus Mantus," "Realdons Columbus," "Hieronymons Fabricins," "Hieronymons Fracastorins," and "Fallopins" (which should be spelt with two p's). And it is strange that the lecturer on public health at St. Bartholomew's Hospital should tell the students that Harvey "probably graduated in 1602." There is nothing uncertain about the date of Harvey's graduation at Padua, which took place on Thursday, April 25th, 1602, as shown on Harvey's diploma, one of the treasures of the Royal College of Physicians.

But these are slight flaws in a charming essay, which had it been dated would not have called forth this letter.—I am, etc.,

London, W., March 25th.

HERBERT R. SPENCER.

* One was published in the BRITISH MEDICAL JOURNAL, 1921, ii, p. 622.

THE late Miss E. Ratcliff bequeathed £10,000 to the Burton-on-Trent Infirmary, which had previously benefited by gifts from her family amounting to £20,000.

THE late Mrs. Elizabeth Clarke of Newton Abbot, who died in November last, leaving net personality of £234,000, has bequeathed £1,000 each to the Newton Abbot Hospital and Dispensary, the Tndor Fund for convalescents in connexion with that hospital, the Moretonhamstead Convalescent Home, and the West of England Eye Infirmary, Exeter, and £500 to her esteemed friend and medical attendant, Dr. William Gifford Scott, for his kindness and unflinching attention. She left her residence, Kanawha, and lands adjoining to her nephew, Dr. Arthur Henry Bindloss, who also receives one-sixth of the residue of her property. The King Edward's Hospital Fund is also to receive one-sixth of the residue of the property.

Obituary.

JOHN TURNER, M.B., C.M.

The death is announced of Dr. John Turner, at the age of 62. He was born at Portsmouth and educated at Aberdeen University, where he graduated M.B., C.M. in 1883. He was connected with the Brentwood Mental Hospital for over 36 years, and was appointed medical superintendent of the institution in 1910. He took great interest in pathological research work, and contributed to our columns articles on vertebral puncture in general paralysis of the insane in 1896, on the pathology of epilepsy in 1926, and on changes in the conception and treatment of insanity in 1912, the latter being his presidential address to the annual meeting of the then East Anglian Branch of the British Medical Association. He also contributed papers to the *Journal of Mental Science*, including one on appearances indicating phagocytosis in brains of the insane, published in 1897, for which he had been awarded the bronze medal of the Medico Psychological Association. On his retirement from Brentwood he went to reside at Rochford, and took a keen interest in the history and antiquities of the neighbourhood, having as recently as February 24th delivered an historical address on Essex windmills. He was a brother of the late Sir George Turner, who was well known in connexion with leprosy research. He is survived by his widow.

Dr. THOMAS HANSON SMITH of Reddish, Stockport, died on March 14th, aged 64. He was educated at Leeds and Manchester, took the diplomas of L.R.C.P. and S.Edin. in 1881 and D.P.H.Camb. 1897, and graduated M.D.Durh. in 1899. After practising for a short time in Bradford and Manchester he removed to Stockport, where he practised for forty years. Before Reddish became incorporated with Stockport he was M.O.H. to the Reddish Urban District Council. He was a Fellow of the Society of Medical Officers of Health and a member of the Stockport, Macclesfield, and East Cheshire Division of the British Medical Association. He was president of the Reddish Conservative Club from 1915 to 1921. Dr. Smith had been in failing health for the last twelve months, and is survived by his widow and two daughters.

We regret to record the death of Dr. CHARLES PINKERTON of Southport, which took place suddenly, at Hastings, in his 65th year. Dr. Pinkerton was a native of Glasgow, and was educated at Glasgow University, graduating M.B., C.M. in 1879, and M.D. in 1882. Some forty years ago he commenced general practice in Southport, and was formerly surgeon (subsequently consulting surgeon) to the Southport Eye, Ear, and Throat Hospital. He was a former president and one of the founders of the Southport Medical Society. Dr. Pinkerton did not take any prominent part in public life; he will be remembered in Southport by his devotion to his patients and his optimistic point of view. He was an old member of the British Medical Association, and was the author of two contributions to our columns on surgical subjects.

Universities and Colleges.

UNIVERSITY OF CAMBRIDGE.

The following candidates have been approved at the examinations indicated:

DIPLOMA IN MEDICAL RADIOLOGY AND ELECTROLOGY.—Part I (Physics and Electrotechnics): E. G. Barker, M. Bienenstock, P. M. Desai, J. A. Garaghty, B. Grellier, S. M. Hepworth, J. P. Thierens, J. A. Thomson, O. H. Unger. Part II (Radiology and Electrolgy): M. Bienenstock, F. T. Burditt, J. D. Kidd, J. S. Levack, Margaret C. Murphy, W. K. Parbury, J. L. Son, J. S. Webster.

UNIVERSITY OF LONDON.

A MEETING of the Senate was held on March 22nd. Mr. C. A. Pannett, M.D., B.Sc.Lond., F.R.C.S., was appointed to the University Chair of Surgery, tenable at St. Mary's Hospital Medical School. He has been Assistant Director of the Surgical Unit at St. Mary's Hospital since 1920.

Mr. C. A. Lovatt Evans, D.Sc.Lond., L.R.C.P., M.R.C.S., was appointed to the University Chair of Physiology, tenable at St. Bartholomew's Hospital Medical College. He has been Professor of Experimental Physiology and Experimental Pharmacology in the University of Leeds since 1917. The degree of D.Sc. in physiology was conferred on Miss E. E. Hewer, an internal student of Bedford College, for a thesis entitled: "Some functions of the suprarenal glands."

UNIVERSITY OF DURHAM.

At the Convocation held on March 25th the following degrees were conferred:

M.D. (For Practitioners of Fifteen Years' Standing).—D. J. Lewis, J. L. Moynell.
M.B., B.S.—A. Angus, F. J. Benjamin, W. N. Crowe, C. G. Carr, J. F. Colman, R. A. McK. Dickson, R. L. Dagger, E. R. Dingle, Barbara M. Gribling, G. A. M. Hall, L. Hunter, J. Jackson, R. W. Locke, T. S. Storey, L. W. Studdy, S. J. C. Smith, Gladys Stableforth, W. P. T. Watts, Olive C. Wilson, Philomena R. Whitaker.

UNIVERSITY OF EDINBURGH.

THE Senatus Academicus of the University of Edinburgh have resolved to offer the honorary degree of Doctor of Laws to the following: Professor Sir Isaac Bayley Balfour, K.B.E., M.D., Professor of Botany, Regius Keeper of the Royal Botanic Garden, and King's Botanist for Scotland; Professor Emeritus Sir Halliday Groom, consulting gynaecologist, Edinburgh Royal Infirmary, consulting physician, Edinburgh Royal Maternity Hospital; Professor Charles James Martin, C.M.G., M.B., D.Sc., F.R.S., Director of the Lister Institute of Preventive Medicine, Professor of Experimental Pathology in the University of London; Professor Sir Charles Scott Sherrington, C.B.E., M.D., LL.D., Professor of Physiology in the University of Oxford; John Thomson, M.D., consulting physician to the Royal Edinburgh Hospital for Sick Children, formerly University Lecturer on the Diseases of Children.

QUEEN'S UNIVERSITY, BELFAST.

At the graduation ceremony on March 22nd the following degrees and diplomas were conferred:

M.D.—J. C. Robb, P. S. Walker.
M.Ch.—J. C. Robb, O. Wilson.
M.A.O.—D. M. Clement.
M.B., B.Ch., B.A.O.—R. I. Poston, †A. H. M'C. Eaton, W. S. Gibson, W. Lascelles, Mary C. Lindsay, I. H. M'W. A. Brown, J. C. Carson, Martha L. Margaret H. Elliott, W. M. Keys, G. M'Cartan, A. E. M'Corkell, A. L. M'Mayne, H. Meharg, Elizabeth Morris, Mussen, Agnes M. Purce, R. B. Quinn, J. Rosborough, T. Savage, C. A. Thompson, C. A. Wallace, D.P.H.—Eileen O'Briley, C. R. Christian, T. H. Crozier, J. H. Dunn, Eileen M. Hickey, J. S. J. Leo, Mary M. Merrick.

* First class honours. † Second class honours.

Medical News.

THE King has approved the appointment of Dr. John S. Griffiths, Redland Park House, Bristol, to be a deputy-lieutenant for Gloucestershire.

A MEETING of the Cambridge Medical Society (members of the Cambridge and Huntingdon Branch of the British Medical Association are entitled to attend) will be held at Addenbrooke's Hospital, Cambridge, on Friday, April 7th, at 2.30 p.m., when cases, specimens, etc., will be shown and discussed.

At the meeting of the Royal Microscopical Society, 20, Hanover Square, W., on April 19th, at 8 p.m., Dr. R. S. Ludford will read a paper on the morphology and physiology of the nucleolus.

At a meeting of the Optical Society at the Imperial College of Science, South Kensington, at 7.30 p.m., on Thursday, April 6th, a paper on diffraction halos in normal and glaucomatous eyes will be read by Mr. H. H. Emsley, B.Sc., and Mr. E. F. Fincham. At the June meeting of the society there will be a discussion on spectacle construction. Further information can be obtained from the joint honorary secretary of the society, Glass Research Association, 50, Bedford Square, W.C.1.

A DISCUSSION on economy in sanitary appliances and methods of drainage will be opened by Sir Henry Tanner, C.B., F.R.I.B.A., at a meeting of the Royal Sanitary Institute, 90, Buckingham Palace Road, S.W.1, on Tuesday, April 11th, at 5.30 p.m.

THE Medico-Legal Society has arranged to establish a library at the house of the Medical Society of London, 11, Chandos Street, W.1. Gifts are invited. The collection will be open to members at convenient hours.

A SUMMER session of the South-West London Post-Graduate Association will begin in May. Particulars can be obtained from the honorary secretary, Dr. H. B. A. Pearson, 29, Bolingbroke Grove, S.W.11.

THE Food Education Society has arranged a discussion at the Caxton Hall, Westminster, on Friday, April 7th, on feeding in institutions with special reference to school diet. It will be introduced by Miss A. D. Muncester, formerly a member of the kitchen inspectorial staff of military hospitals. Sir William Collins will take the chair at 5.30 p.m.

SIR THOMAS LEWIS will deliver the Noble Wiley Jones lectures under the auspices of the medical school of the University of Oregon, U.S.A., between May 15th and 19th; the lectures will deal with auricular fibrillation, quinidine and digitalis.

A FAREWELL dinner is to be given to Dr. James Niven, lato medical officer of health of Manchester, by the members of the medical profession in Manchester. It has been decided that the guests may include members of the medical profession and persons connected with the Manchester Corporation, University, and Insurance Committee. The dinner will be held on Tuesday, April 11th, at the Queen's Hotel, Manchester, at 8 p.m., and tickets (15s. each) may be obtained from Dr. R. G. McGowan, Union Bank Buildings, Piccadilly, Manchester.

AT the instance of the International Labour Office a meeting was held recently in Geneva to consider various problems relating to men disabled in the war or in industry. The meeting was attended by representatives of organizations of ex-service men and official departments concerned with disablement in France, Great Britain, Italy, Poland, Germany, and Austria, and by representatives of the Health Section of the League of Nations and of the League of Red Cross Societies. The meeting expressed an opinion in favour of the establishment of an international institution to collect information and to organize an international exhibition of artificial limbs and other orthopaedic instruments. The meeting was of opinion that legislation concerning industrial accidents should be amended so as to allow men disabled in industry to have the benefit of the experience gained during the war, and to this end advised co-operation between departments dealing with the supply of artificial limbs and orthopaedic instruments to disabled ex-service men on the one hand and social insurance organizations on the other. It considered that the departments established for the benefit of ex-service men should to some extent be maintained permanently. It is hoped that the exhibition, when once the materials have been gathered at Geneva, will visit other countries.

THE Board of Control, with the approval of the Minister of Health, has appointed a committee to consider the clinical and other records kept in county and borough mental hospitals, and to report in what ways the system of keeping them can be improved and what alterations in the Commissioners' rules in regard to them are desirable. The members are Dr. A. Rotherham, M.B. (Chairman), Commissioner of the Board of Control; Dr. H. A. Kidd, C.B.E., medical superintendent, West Sussex County Mental Hospital, Chichester, and Dr. S. J. Gillilan, O.B.E., medical superintendent, London County Mental Hospital, Colney Hatch. The Board has also appointed a committee "to consider the dietaries in county and borough mental hospitals, and to report what changes, if any, are desirable, and whether a minimum dietary scale should be fixed." The members are: Dr. R. W. Branthwaite, C.B., M.D. (Chairman), Commissioner of the Board of Control; Dr. M. Greenwood, medical officer (medical statistics), Ministry of Health; Dr. R. Worth, O.B.E., M.B., medical superintendent, Springfield Mental Hospital, Tooting; and Dr. L. O. Fuller, medical superintendent, Three Counties Mental Hospital, Arlesey, Beds. The following members have been added to the committee which is to inquire into the nursing service of mental hospitals: Mr. E. Sanger, ex-Chairman of the London Asylums Committee; Mrs. Pinsent, Commissioner of the Board of Control; Miss M. M. Thorburn, R.R.C., matron at Horton Mental Hospital.

DR. F. J. PEARSON of Owston Ferry, Doncaster, has been presented with a cheque for £56 by friends and well-wishers. The presentation was made by the Bishop of Grantham, and at the same time Mrs. Pearson was presented with a gold brooch set with pearls.

THE report of the Royal Portsmouth Hospital for 1921 contains the following: "The Committee record with deep regret the death of Dr. J. Ward Cousins, J.P., who was on the active staff of the hospital for forty-eight years, retiring in 1903, when he was elected a consulting surgeon and also a vice-president. He worked successfully for the interests and development of the hospital. A surgeon of exceptional ability, his professional services were of the highest order, whilst his keen judgement and ardent zeal were of the greatest value in the movement which led to the building of new wards and the reconstruction of the old building. His work in connexion with the hospital will stand as a living memorial of his name."

THE number of deaths from influenza continued to decline in the week ending March 25th; in the 105 great towns there were 104 deaths from the disease, as against 146 in the preceding week; in London the number was 17, as against 21 in the week ending March 18th.

DR. EDWIN RAYNER, at one time treasurer of the British Medical Association, left estate of the value of £42,241.

THE Ligue d'Hygiène Mentale, founded in Paris to promote the early and preventive treatment of mental disorders, has succeeded in securing the establishment of several dispensaries in the Department of the Seine.

THE editor of *Industrial Welfare* informs us that at the present time more than 200 firms are publishing welfare magazines. The firms include engineers, iron and steel manufacturers, collieries, ship builders, millers, food stuff manufacturers, banks, textile firms, railways, and distributing firms. A conference of editors of such magazines has been arranged by the Industrial Welfare Society and will be held at its offices, 51, Palace Street, Westminster, on April 28th.

THE "Holy Rollers" are a sect new to us; the members believe that diphtheria can be cured by faith. An epidemic of the disease at Prentiss, Maine, U.S.A., is attributed to the belief of the parents of a sick child in this doctrine. The child died, and within a few days there were ten cases of diphtheria in the immediate vicinity.

AT the examination held recently for the diploma of membership of the Society of Radiographers there were forty-five candidates, of whom seventeen passed in both sections. The next examination is to be held in July. Two prizes of ten guineas and one of five guineas were awarded for theses by members of the society on radiographic subjects.

PROFESSOR EHLERS of Copenhagen has received the honorary degree of doctor from the University of Paris.

THE German Congress of Surgery will be held at Berlin, under the presidency of Professor Hildebrand, from April 19th to April 22nd, when the following subjects will be discussed: The experimental principles of wound infection, introduced by Nenfeld of Berlin; general surgical infection, introduced by Lesser of Freiburg; operative transplantation of muscles, introduced by Wallstein of Essen; and the importance of histological examination of the blood, introduced by Stahl of Berlin. The thirty-fourth meeting of the German Society of Internal Medicine will be held at Wiesbaden from April 24th to April 27th, under the presidency of Professor L. Brauer. The chief subjects for discussion will be jaundice, introduced by Professor Eppinger of Vienna, and the hypophysis, introduced by Professor Biedl of Prague.

Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR OF THE BRITISH MEDICAL JOURNAL, *Atiology*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Medisera*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Circular Road, Dublin; telephone, 6, Rutland Square, Edinburgh telephone, 4361, Central).

QUERIES AND ANSWERS.

DR. DIXON (Hawick, N.B.) would be glad to hear from any professional brother willing to exchange bookplates.

DR. W. J. MIDELTON (112, Charmingston Road, Bournemouth) asks for references to papers describing the condition of the brain, spinal cord, nerves, muscles, blood vessels, and lymphatics, in chronic arthritis.

INCOME TAX.

"J. S. B." is considering the purchase of a practice, and inquires as to the basis of assessment in the early years after the change.

"* For his first year he is liable to be assessed to tax on the basis of his predecessor's past profits for three years, for the second year on the basis of his predecessor's last two years and

recurrences (6 per cent.). Recurrence is generally due to infection. This operation is valuable, as it gives the advantages of the operation by the inguinal route without the technical difficulties. It is a simple procedure, easy to carry out, convenient for all types of case, and deserves to be more widely employed.

309. Abdominal Hernia.

FRANK (*Amer. Jour. of Surgery*, January, 1922) states that inguinal hernia is the most common variety seen, femoral hernia being the next in frequency. It is now the accepted belief that abdominal hernias exist potentially from birth and a strain forces the contents into a pre-existing sac. It is therefore often advisable to repair both sides at operation. The cause of recurrence in many instances is that surgeons do not adapt their operation to the particular type of hernia—that is, direct or indirect—but follow one set plan. Direct hernias are more liable to recur after operation. Recurrence takes place in about 1 per cent. of all cases, being slightly more frequent after the Ferguson than the Bassini type of operation. In direct hernias and in old hernias with a large opening it may be necessary to split the sheath of the rectus and use it for reinforcing the canal. Hernias which recur within six months are due to septic infection or where a wrong type of operation has been performed. Most recurrences take place in aged individuals, and in them removal of the testicle and cord is desirable to permit complete anatomic closure of the canal. In femoral hernia Frank never closes the ring and never sees recurrence. The operation of Mayo promises almost a sure cure for umbilical hernia, and the risk of recurrence is very slight. In strangulated or incarcerated hernia the danger of delay cannot be too strongly accentuated. Taxis should only be employed on the operating table. In patients in *extremis* it is best to make an artificial anus and later complete the operation by resection and closure of the opening. In treating the sac, in inguinal hernia, it is best to free the neck, transect it, and fasten this with the suture well upwards under the conjoined tendon. This eliminates the funnel-like process so potent in the production of hernia. If the distal end is adherent, leave it alone: no trouble ensues. In children a well-fitting truss is applied, in the hope that with muscular development the hernia will close early in life. Should a cure not result, operation is undertaken after 3 years of age. For dressings no pad is placed over the incision, as this causes interference with nutrition and delayed healing. Likewise no truss is used post-operatively. Rest in bed for from two to three weeks, followed by cautious resumption of exercise, should result in less than 1 per cent. of recurrence. The operative mortality is practically nil.

CLARK (*Am. Journ. Med. Sciences*, February, 1922) points out that relatively slight saluting attacks, at times simulating petit mal, occur in some rapidly growing adolescents. There appears to be an excessive functioning of the anterior lobes of the pituitary gland in such cases, accompanied by low blood pressure, slow pulse, and vasomotor ataxia, and often slow mental development. Improvement usually follows outdoor living and long hours of sleep, and, in some cases, the administration of post-pituitary and thyroid gland substance. Slow and incomplete loss of consciousness, preceded by dizziness, palpitation, and a sinking cardiac uneasiness, the absence of convulsions and after-effects—for example, transitory automatism, stupor, etc.—distinguish the condition from epilepsy. Many of the slighter grades of the condition improve without definite treatment, the other ductless glands curing the hypophyseal imbalance by atrophy of the thyroid or excessive functioning of the adrenals.

308. Radical Cure of Femoral Hernia.

The large number of operations described for the cure of femoral hernia is perhaps the best proof of the inadequacy of most of them. It is not always easy to obtain, by a simple operation, the absolute cure of a hernia, for if several methods give satisfactory end-results they are, as a general rule, difficult to carry out. For this reason PROTOWSKI (*Lyon Chirurgial*, November-December, 1921) compares with other methods the results obtained by means of the suture-in-U, which operation is marked by its simplicity. This procedure, based on anatomical lines, aims at closing the crural ring, and has been adopted in several clinics, but is unfortunately not widely known. The incision is made parallel to Poupart's ligament, slightly below it and across the swelling. The sac is identified and freed from preperitoneal fat as high as possible. The sac is then opened and the contents reduced after careful examination, Gimbernat's ligament being divided if necessary. If the hernia contains strangulated gut and a resection is indicated, this is done and an end-to-end anastomosis performed. If only a small area is affected this may be infolded. In ligaturing the sac it is advisable not to pull it down too much for fear of wounding the bladder. To perform the radical cure a Reverdin needle is passed from just above Poupart's ligament through the abdominal muscles. The index finger of the left hand is introduced into the crural canal and pushes up the stump of the sac. The needle is then passed on to this finger, which defines the ring. The finger is next slightly withdrawn and the needle passed so that it just grazes the pubic bone, going through Cooper's ligament and picking up the periosteum if possible. The needle is threaded and withdrawn. A little to the inner side of this point it is reintroduced and the same procedure carried out. The two ends of the suture are then tied, but not too tightly. If the ring is large a second suture may be necessary. The abdominal muscles are thus drawn down to Cooper's ligament and close the opening between the abdominal cavity and the crural canal. The wound is then sutured and the sutures removed about the eighth day. Out of 66 cases which he has been able to trace, there were four

310. End-Results of Tonsils and Adenoids Operations.

310. **End-Results of Tonsils and Adenoids Operations.**
WRIGLEY and ARCHER (*Journ. Laryngol. and Otol.*, March, 1922) record the end-results of 220 consecutive cases of tonsils and adenoids treated by operation; in all cases at least a year had elapsed between the operation and the final examination. The majority were treated as out-patients, only those over 15 years of age, or living more than three miles away, being detained for a night. Tonsillectomy under daylight illumination, with as little swabbing as possible, was performed in all the cases with O'Malley's blunt tonsillotome, the adenoids being removed with a eaged curette, and in no instance was it necessary to adopt measures to check hæmorrhage either at the operation or later; in the great majority there was no local after-treatment. The indication for and results of operation included 128 cases of nasal obstruction and mouth-breathing, in which all symptoms were relieved except in three; 34 cases of tonsillitis, all relieved; 93 cases of non-suppurative deafness, all cured except 7; 39 cases of suppurative otitis media, all relieved except 11; 7 cases of enlarged cervical glands, all cured but one; and 7 cases of quinsy, all cured. Tonsils completely removed did not recur, but in 6 cases the lower pole of the tonsil remained through incomplete removal. Adenoids recurred in 3 cases, but in only one was recurrence sufficient to require further operation. In aural lesions the operation resulted in recent perforations drying up and the resolution of mucous catarrh.

311. Chronic Lumbago of Traumatic Origin.

311. **Chronic Lumbago of Traumatic Origin.**
 ACCORDING to MARTIN and JUVIN (*Journ. de méd. de Lyon*, November 20th, 1921), who record four illustrative cases, apart from muscular lesions and fractures caused by laceration or crushing of the vertebrae, injuries to the vertebral column may affect a structure which is previously healthy and give rise to a traumatic spondylitis, in which case the trauma is entirely responsible for the patient's condition. On the other hand, if the trauma is applied to a vertebral column which already presents clinical evidence of disease, the trauma should be regarded merely as an aggravation of the pre-existing disease. Lastly, there are certain chronic

vertebral affections, especially of a rheumatic nature, which have a very insidious course, and give rise to a progressive deformity of the vertebrae without any clinical signs, but are visible on x-ray examination, which reveals a new growth of bone. Traumatism by breaking these new growths gives rise to a chronic vertebral arthritis, which is the cause of constant pain and permanent and partial disability. The latter should be attributed entirely to the trauma without taking the previous condition of the patient into account.

312. Infantilism in Chronic Appendicitis.

CIGNOZZI (*Rif. Med.*, January 16th, 1922), out of 500 cases of appendicitis treated surgically, has collected 15 who showed signs of infantilism. The appendix symptoms were those usually associated with a chronic type, and the dystrophic symptoms and signs usually appeared between 8 and 12 years of age. Photographs of the condition are given. Removal of the appendix cures the dystrophic condition. The parietal peritoneum in these cases is much thicker than normal, and as a rule the appendix is exceptionally long (12 to 15 cm.) and voluminous, with apical dilatation. The caecum, too, is in 90 per cent. of the cases dilated. Boys are more often affected than girls.

313. The Diagnosis of Intestinal Tuberculosis.

LOLL (*Wien. klin. Woch.*, January 19th, 1922) gives the results of numerous examinations of the faeces, with respect to the value of the detection of occult blood and of tubercle bacilli in the diagnosis of intestinal tuberculosis. He found that in all cases of tuberculous ulceration of the intestines occult blood could be detected in the faeces by the benzidin test, after a diet which had been free from any food containing haemoglobin for six or seven days. From the results of his observations he concludes that examination of the faeces for tubercle bacilli, as an indication of intestinal tuberculosis, is useless, since the tubercle bacilli found in the faeces are chiefly due to the patient swallowing his own sputum, which contained tubercle bacilli. In cases of extensive tuberculosis of the intestines, when the pulmonary disease has not caused the sputum to contain tubercle bacilli in large numbers, then the faeces have contained few tubercle bacilli, or generally none at all. When the expectoration has been free from tubercle bacilli the faeces have been found also free from tubercle bacilli, although extensive intestinal tuberculosis has been present.

314. Indications for Operation in Cholelithiasis.

DE MARTEL and ANTOINE (*La Médecine*, October, 1921) state that operation may be required in the following groups of cases: (1) Patients in whom attacks of gall-stone colic occur at frequent intervals and are accompanied by progressive loss of flesh. (2) Cases characterized by chronic and progressive jaundice, which is not relieved by medical treatment. In such cases incision of the bile duct over the calculus may be sufficient; but if the patient's condition allows it, cholecystectomy should be performed. (3) Febrile cases—(a) in suppurative cholecystitis cholecystotomy should be performed under a local anaesthetic, followed by a cholecystectomy later; (b) in angiocholitis medical treatment should be employed at first, as the operation mortality is 50 per cent., but if the general condition gets worse operation is imperative.

OBSTETRICS AND GYNAECOLOGY.

315. Primary Cancer of the Vagina.

ENGELKENS (*Nederl. Tijdschr. v. Geneesk.*, January 7th, 1922) states that numerous statistics show that primary cancer of the vagina is a very rare occurrence. It is often difficult to determine whether the tumour has developed from the vaginal epithelium or from the cervix, and in advanced cases it is quite impossible. According to the statistics of Gurlt, Hecht, Rohde, Howuth, and Kalle, about 1.5 per cent. of all cancers of the sexual organs arise from the vagina. Kalle alone gives a figure of 0.26 per cent., obtained from a study of all the cases treated in the clinics of Berlin, Halle, and Vienna. According to Sehnd, who has collected 260 cases, the largest number of patients are to be found between the ages of 30 and 40, and 50 and 60. Asehheim reported a case in an infant of 6 months. The etiology is obscure, as in other forms of malignant growths. Pessaries have been incriminated. Meyer, Schmidt, and Winekel have each described cases in which a pessary has given rise to a pressure sore on which a cancer has developed. The favourite site for the tumour is the posterior wall of the vagina, especially the posterior third. In addition to a local form commencing as a solitary nodule, which subsequently breaks down and forms an ulcer, there is a diffuse infiltrating form which Sehnd found in 20 of his 184 cases. Engelkens himself

records a case of this kind in an unmarried woman, aged 35, which developed shortly after injection of pure lysol by an abortionist in early pregnancy. Usually vaginal cancers consist of pavement epithelium, but sometimes they are glandular carcinoma derived from the glands of the cervix or the remains of Gartner's ducts. One of the earliest clinical signs is a mucœ-haemorrhagic discharge, especially after coitus. It is not till a late stage that pain develops in the abdomen, loins, and legs, and last of all a vesical or intestinal fistula forms. According to Winekel the condition must be distinguished from condylomata, suppurating myomata, and tertiary syphilitic lesions. Owing to the rich lymph supply of the vagina and the fact that the condition is usually not recognized until late, the prognosis is very grave. Treatment consists in the combination of operation and x-ray therapy.

316. Routine Podalic Version.

SPEIDEL (*Amer. Journ. Obstet. and Gyn.*, February, 1922) describes the technique of Potter's version, and discusses its application. Potter has not specified contraindications to his method and advocates its use as a routine in almost every head presentation, the object being to spare the mother the pain accompanying the second stage of labour; he used his method in over 900 of his 1,030 last year's deliveries, with a foetal mortality of 2.3 per cent. The method is as follows: The patient is fully anaesthetized with chloroform and placed in the modified Waleher position; after disinfection the vagina is "ironed out" by introducing the left hand and stroking the posterior wall downwards with increasing degrees of pressure. Green soap is used as a lubricant. The left hand, covered by a glove reaching to the elbow, is introduced within the uterus through the fully dilated cervix, being passed between the uterine wall and membranes and avoiding the placenta. The membranes being broken through near fundus, the hand is made to slide down the thighs of the foetus until the feet are reached; by means of gentle traction, aided by pressure of the right hand, applied through the relaxed abdominal wall, the version is completed by bringing both feet out of the vagina. The essential feature of a delivery of the arms by this method consists in first delivering the anterior arm by means of slipping a finger along the shoulder under the symphysis pubis; the body is now turned so that the posterior arm comes to rest under the symphysis and is delivered in the same manner as the first shoulder. The head is delivered by inserting two fingers of the left hand into the baby's mouth, the body riding astride of the left arm; with the right hand resting on a towel suprapubic pressure is made downwards and backwards until the face distends the vulva. The feet are now held high, and in many instances the foetus begins to breathe while in this position. At this stage there should be no undue haste, and the head may be allowed for a time to dilate the perineum. Vigorous manipulation of cyanosed infants is not advised; they should be placed, quietly lying on their right side, on the maternal abdomen and the cord should not be tied until its pulsation ceases. An injection of pituitary extract is made immediately after completion of the second stage. Speidel does not favour the use of Potter's method in normal vertex cases, but finds indications for it in all face presentations and in the majority of occipito-posterior positions. When, however, podalic version has to be performed he believes that the Potter method is superior to all others. He concludes also that the Potter methods of delivery of the after-coming arms and head are of very considerable value. It has been claimed in justification of the unorthodox method of delivering every case of head presentation by version that the danger of foetal cerebral haemorrhage, due to prolonged pressure during the second stage of labour, is minimized.

317. An Explanation of Colles's Law.

ACCORDING to FEHLING (*Zentralbl. f. Gynäk.*, February 4th, 1922) it is no longer justifiable to hold, according to Colles's law, that the mother of a foetus whose father is syphilitic is thereby rendered immune to syphilis. In these cases the maternal blood shows a positive Wassermann reaction and spirochaetes are to be found in the maternal portions of the placenta; these organisms are too large to be carried in the head of the spermatozoon. Further, Uhlenhuth has produced in rabbits testicular syphilis by injection of the blood or milk of mothers who show Colles's phenomenon. It is therefore to be concluded that these women are not immune but latently syphilitic; the fact remains that manifestly syphilitic sires are lacking in from 20 to 39 per cent. of them. Having regard to the frequency of primary sores of the portio and to the frequency of endometrial infection, the writer suggests that infection takes place during the weeks following conception, by reason of the introduction through the seminal fluid of attenuated spirochaetes into the

no defective digestion or insufficient absorption of fat in rickets. On the whole the author considers that mere deficiency of fat-soluble vitamins cannot be accepted as the sole or chief cause of rickets.

321. Tar Cancer in Mice.

ROUSSY, LEROUX, and PEYRE (*Bull. de l'Assoc. française pour l'Étude du Cancer*, January, 1922) publish a preliminary communication concerning their researches into the experimental production of tar cancer in mice; the paper is well illustrated, and gives the history of experiments on 86 mice. In the first series, which have been observed for 240 days, the tar was painted over small areas on the nape of the neck, the tar being applied every second day on a glass rod; 14 mice were used, and 8 did not show any tumours, but the remainder have developed definite epitheliomas of the skin. In the second series, which have been observed for 190 days, the tar was applied in the same fashion to 12 mice, of which after the lapse of this period of time 7 mice have shown cancerous changes. The third series of 60 mice have been under observation for 108 days, and in these, the tar was painted in a streak from the neck to the root of the tail every second day; the majority of these now exhibit an atrophic dermatitis, and three have shown definite hyperplastic projections. The low mortality experienced amongst these mice the authors attribute to the fact that they did not employ depilatory measures (as carried out by workers in this country) before applying the tar. Attempts at propagation by grafts have not yet been successful, but the authors do not attach much importance to this.

322. Haemolytic and Water Fevers.

SOME work has been performed by PENFOLD and ROBERTSON (*Med. Journ. of Australia*, January 14th, 1922) to determine whether the occurrence of haemolysis in the body is able to give rise to pyrexia. Twelve experiments were conducted on rabbits, in which quantities of carefully prepared glass-distilled water, varying from 5 c.cm. to 52 c.cm., were injected intravenously. Haemoglobin appeared in the urine within thirty to forty minutes, and persisted in some cases for as long as six hours. The temperatures of the animals were taken per rectum every half-hour for six hours after the injections. In no case did any rise in temperature take place. From these experiments they conclude that no reliable evidence of pure haemolytic fever exists; and that in consequence the fever in paroxysmal haemoglobinuria must be due to some other cause. Owing to the recognized fallacies inherent in drawing conclusions from one species of animal to another, it would seem that such an inference is quite unjustified.

323. Destruction of Tuberculous Sputum. .

MESSERSCHMIDT (*Deut. med. Woch.*, February 23rd, 1922) has tested at a bacteriological laboratory in Hanover the action of all the well-known disinfectants on tuberculous sputum, and has invariably found them useless. Mercurial compounds, carbolic acid, bacterial stains, chinolol, potassium permanganate, and many other familiar disinfectants were tested, and the results were invariably disappointing until the author investigated the claims made by Professor Uhlenhuth on behalf of an alkaline lysol. This preparation, which contains about 4 per cent. sodium hydroxide and 65 per cent. kreosole, disintegrates mmular sputum so that the tubercle bacilli are not protected by a thick sheath of coagulum. To 50 c.c.m. of mmular sputum the author added 100 c.c.m. of a 5 per cent. solution of Uhlenhuth's alkaline lysol, and after this mixture had stood for four hours in the cold, guinea-pigs were inoculated subcutaneously with it. Eight weeks later they were found to be perfectly free from tuberculousis, whereas control guinea-pigs showed advanced tuberculousis.

324. The Antitryptic Power of the Blood in
 Anaphylactic Shock.

Anaphylactic Shock.
In view of the contradictory reports issued by various workers on the antitryptic titre of the blood in anaphylactic shock LAUNOY and FALQUE (*C. R. Soc. Biologie*, January 21st, 1922) have endeavoured by fresh experiments on the subject to clear up the confusion. After ascertaining the normal antitryptic titre of the blood in guinea-pigs they proceeded to sensitize four of these animals to horse serum by means of the subcutaneous injection of antidiphtheritic serum. Three weeks later the dechaining dose was given intravenously. A control animal died in just over four minutes from acute shock. On the other three animals carotid puncture was performed at various times before and after the shock, and estimations of the antitryptic titre were made on each sample. The results all agreed in showing that at no stage was there any appreciable alteration from the titre previously determined for normal guinea-pigs.

Presidential Address

ON

THE RISE AND PROGRESS OF LARYNGOLOGY:

ITS RELATION TO GENERAL MEDICINE AND ITS POSITION IN THE MEDICAL CURRICULUM.

DELIVERED BEFORE THE MANCHESTER MEDICAL SOCIETY

BY

SIR WILLIAM MILLIGAN, M.D., C.M.,

AGRICULTURIST AND LARYNGOLOGIST, ROYAL INFIRMARY, MANCHESTER; LECTURER ON DISEASES OF THE THROAT AND EAR, VICTORIA UNIVERSITY, MANCHESTER; PRESIDENT, LARYNGOLOGICAL SECTION, ROYAL SOCIETY OF MEDICINE.

SPECIALISM in medicine or surgery is no new-fangled idea. Herodotus, the Father of History, writing more than 2,500 years ago of the highly developed state of specialism amongst the Egyptians, says:

"Physicis is so studied and practised with the Egyptians that every disease has its several physician who striveth to excel in healing that one disease and not to be expert in curing many. Whereof it cometh that every corner of that Country is full of physicians, some for the eyes, others for the head, many for the teeth, and not a few for the stomach and the inwards."

In those far-off days the human body was divided into some thirty-six regions, with specialists for each one of them, and history records that jealousy existed amongst specialists when they invaded one another's territory—a state of affairs not unknown even to-day. In the Ebers Papyrus, compiled about 1550 B.C., the anatomy and physiology of the nasal passages are described as follows: "There are four vessels in both nostrils, of which two carry blood and two mucus. Once air has entered the nose it is lost sight of; it goes to the heart and to the rectum."

Closely allied with Egyptian medicine was that of the Chaldeans and Assyrians, tainted very largely, however, with witchcraft and sorcery—for example, "gargling with the milk of a sheep helps the tonsils and the fauces, anginas are helped by a goose's gall mixed with claterrum and honey, by the brain of an owl, and by the ashes of a swallow soaked in hot water."

In *La Médecine du Talmud* we are told that a transverso incision of the trachea is fatal, whereas a longitudinal one is not.

Among the Hindu races the surgery of the throat attracted much attention and many weird forms of treatment. Wise, in his book on the Hindu system of medicine, describes a method of tonsillotomy which aimed at removing a third part only with the knife—"if all is cut the patient will die of hæmorrhage." The removal of foreign bodies from the food and air passages was not only attempted but accomplished, the method consisting in passing a hot iron through a metallic tube to dissolve or soften and so to remove it. I can find no mention of the end-results of such drastic performances—no mention of any resulting stenosis or of adhesions; evidently there were no follow-up-case committees at work in those days.

Although Homer does not mention the word "larynx," it is freely mentioned by other Greek writers. Aristotle (384–322 B.C.) describes it as the organ through which the voice and the breath pass. "It is the voice and larynx which emit vowels; it is the tongue and lips which form the consonants or the aphonic letters."

Hippocrates, who, according to Celsus, was the first medical specialist, described the epiglottis as a process in the form of an ivy leaf which prevented liquid entering the larynx and kept it in the pharynx; and of the trachea he said that it was cartilaginous, surrounded by smooth rings, and contained but little blood.

The etiology and treatment of nasal polypi has from time immemorial even up to the present day been responsible for much controversy. Cato the Censor, writing 232 B.C., says:

"If there is a polypus in the nose rub together some wild cabbage leaves in the hand, place them in the nose and draw up the breath as much as you can. In 3 days the polypus will fall away." Nevertheless for some days do the same so that you may render the roots of the polypus entirely healthy."

Celsus used a sharp spatula-shaped instrument to separate the growth from the underlying bone and then extracted it with a hook. Hippocrates, on the other hand, recommended tying a sponge to a string, passing the string through the

nasal passages and out through the mouth, in order forcibly to draw the polypus from its attachments. For hard growths the loop of a sinew was passed round the attachment of the growth and then tightened. Subsequently cauterization was employed, a hot iron being passed through a metal tube and the raw surfaces seared. Following one or other of these methods of removal he advised the use of copperas powder and the insertion of tents smeared with oil and honey into the nostrils. He says: "Those diseases which medicines do not cure the knife cures; those which the knife cannot cure fire cures; those which fire cannot cure are to be reckoned wholly incurable."

Curiously enough, in the Hippocratic treatises there is no mention of tonsillotomy, but in *The Prognostics*, No. 23, the operation of uvulotomy is described: "When the uvula alone is inflamed seize it with the finger, press it up against the palate and cut off the end." Other Greek writers, however, describe tonsillotomy in detail. Thus Albucasis writes:

"If they [the tonsils] are of a dark colour and of slight sensibility do not touch them with the knife, if red and the base is broad do not touch with a knife for fear of hæmorrhage but delay until it has ruptured for then thou canst perform it or it will break of itself. But if it is of a white colour, round and has a slender base this is the kind which is suitable and thou shouldst cut it."

That great bogbear of the rhino-laryngologist, atrophic rhinitis or ozaena, was not only recognized as a distinct pathological entity but was vigorously treated. Celsus says:

"If these ulcers are around the openings and have many crusts and have a foul odour which variety the Greeks call Ozaena it should be recognized that it is hardly possible to cure this disease. In the nostrils let honey be applied with a small amount of resin of turpentine which may be used on a probe wrapped with wool. By the use of this the crusts are loosened and may then be removed by the use of sternutories."

He advised leaving pledgets of lint saturated with medicaments in the nostrils, twice a day in winter and spring, and thrice a day in summer and autumn.

The first definite description of tracheotomy is from the works of Antyllus, who lived during the reign of Hadrian (117–138 A.D.). Adams translates as follows:

"In cases of croup the we entirely disapprove of this operation because the incision is wholly unavailing when all the arteries (the whole of the trachea and bronchi) and the lungs are affected, but in inflammation about the mouth and palate, and in cases of indurated tonsils which obstruct the mouth of the windpipe, as the trachea is unaffected it will be proper to have recourse to pharyngotomy in order to avoid the risk of suffocation. When therefore we engage in the operation we slit open a part of the arteria aspera (for it is dangerous to divide the whole) below the top of the windpipe about the third or fourth ring. For this is a convenient situation as being free of flesh and because the vessels are placed at a distance from the part which is divided. Wherefore bending the patient's head backwards so as to bring the windpipe better into view we are to make a transverse incision between two of the rings so that it may not be the cartilage which is divided but the membrane connecting the cartilages. If one be more timid in operating one may first stretch the skin with a hook and divide it, and then removing the vessels aside if they come in the way make the incision."

Galen described twelve intralaryngeal muscles—that is, six pairs—and enumerated three cartilages of the larynx: the thyroid, the cricoid, and the arytenoid; the latter he supposed was a single cartilage. He claims to have discovered and described the ventricles of the larynx. He describes also the vocal cords as a membranous substance so constituted as to resist the impact of the air and lubricated by mucus to prevent injury from the vibrations of a dry surface. He was the first to describe the recurrent laryngeal nerves. He considered that chilling of the recurrent nerves during operations damaged the voice, and he therefore advised against operations in this region during cold weather. He recognized the dependence of diseases of the larynx upon affections of the parts above, but explained it on the assumption that the brain was the common origin of all catarrhs. Paulus Aeginetus introduced the knotted-string method for the removal of polypi.

"Taking then a thread moderately thick like a cord, and having tied knots upon it at the distance of two or three fingerbreadths, we introduce it into the opening of a double-headed specillum [probe] and we push the other extremity of the specillum upward to the ethmoid opening."

In the great medical school of Salerno the surgery of the throat came in for a considerable share of attention. Roger of Parma, whose *Practica Chirurgica* saw the light about the

beginning of the thirteenth century, thus describes the treatment of a tonsillar abscess:

"Seat the patient before you and press his tongue down in his open mouth with an instrument so that you can see the tonsils well. Take hold of the affected one firmly with a bronzed iron hook and incise it with a properly sharpened instrument. Leave the coverings the pillars of the fauces, which stand next to them uninjured however."

He even anticipated the much debated present operation of complete emelation when he says, "et a radice funditus extollatur"—plucked away entirely by the roots.

Of an elongated uvula which could not be made to contract as the result of local medication he wrote:

"It should be grasped with a forceps made for the purpose near the palate where the uvula itself is sometimes of smaller diameter and snipped off. Care should, however, be taken not to touch the root of the uvula."

His method of treating "scinancia," literally translated retro-pharyngeal abscess, would hardly, however, appeal to the modern laryngologist:

"Take of salt beef half cooked of the size and shape of a chestnut or a fig, and having fastened it firmly by a long silken cord have the patient swallow it, and then let the physician pull it out suddenly and violently [cum violentia] in order that the abscess may be ruptured."

In 1252 Bruno of Longoburgo published his *Chirurgia Magna*, in which he describes several varieties of nasal polyp, one of them of dark colour, slight sensibility, and hard, which he regarded as malignant and advised leaving alone. He suggests that the root of the simple polyp be cauterized with a hot iron or with some cauterizing material. He seems to have anticipated Meyer's discovery of adenoids, and quotes Paul of Aegina's method of dealing with post-nasal growths—namely, that a ligature with knots at intervals be passed through a tube into the nose and brought out again through the mouth and a to-and-fro motion be used to cut off the projecting growths at the back of the nose. The originator of the term "union by first intention" ("unio per primam intentionem"), he realized that wounds should heal without pus formation, and regarded purulence as the fault of the surgeon.

Theodoric, a pioneer in plastic surgery, used strong wine as the only dressing. A bishop as well as a surgeon, he was the first writer definitely to mention anaesthetics for throat and other operations, assigning their introduction to his father, Hugh of Lucea:

"Having made a mixture of the wine extracts of opium, hemlock, mandragora, nupur, mulberries, and wild lettuce a sponge should be boiled in this fluid until all is boiled away, and then wherever anaesthesia is wanted this sponge should be placed in warm water for an hour and applied to the nostrils until the patient sleeps, when the surgical operation should be performed. At its end another sponge dipped in vinegar should be frequently applied to the nostrils or some of the juice of the root of haw should be injected into the nostrils, when the patient will soon awaken."

In the Middle Ages, as now, the treatment of catarrh and coryza was the subject of much speculation, of many remedies, and of much disappointment. Gregory Horst, a prolific writer about 1660, highly extolled the medicinal properties of tobacco. He declared that the inhabitants of Florida at certain specified seasons of the year live on the smoke of this plant, which they receive into the mouth through horns prepared for the purpose, whereby, they assert, hunger and thirst are stilled and an incredible amount of phlegmatic humours are collected in the mouth.

When it (the smoke) is taken into the mouth through a pipe stein it pervades the whole brain and even the uterus. One of its signs of its efficacy is the paleness of the countenance.

Fabrizius Aquapendente (1537-1619) in *Opera Chirurgica*, after criticizing the treatment of ozaena as advocated by Celsus, writes as follows (edition of 1723, cap. xxvi):

"An iron cannula is to be inserted in the Nostril so long that it will reach the end and equal the length of the ulceration and occupy the cavity of the Nostrils: through this a glowing hot instrument is to be introduced which however should not reach beyond the cannula, it should be so done that the hot iron heats the tube and through this the nasal tissues and the ozaena. It is not intended that the Nose should suffer from this heat but only that the ulcerated part should be heated to a point short of pain in one having a good tolerance. This being perceived the cannula may be taken out of the nostrils the secretions cleaned off and then replaced."

He also regarded tonsillotomy as performed by Celsus and Paulus Aegineta as neither safe nor easy. He advises

seizing the tonsil with a long slender forceps to draw it out, so that by skilfully making traction the tonsil as if of its own accord will follow.

The operation of tracheotomy, although described by Arabian, Greek, and pre-Renaissance writers, does not appear to have been actually performed until the middle of the sixteenth century. Its first performance has been ascribed to Beniveni, who died in 1502, but according to Casserius (1600) it was Brasavola who first opened the trachea (in 1545); his dictum being: "When there is no other possibility in angina of admitting air to the heart we must incise the larynx below the abscess" (Holmes). Casserius remarks that those who rejected bronchotomy are "inhuman, awkward, timorous, and are even, as it were, to be held as homicides." Fabricius says:

"Of all the surgical operations which are performed on man for the preservation of his life by the physician I have always judged to be foremost that by which man is recalled from a quick death to a sudden repossession of life, a feat which raises the surgeon nearest to the level of Aesculapius—that operation is the opening of the aspera arteria by which patients from a condition of almost suffocating obstruction to inspiration suddenly regain consciousness and draw into their heart and lungs that vital ether, the air, so necessary to life and again resume an existence which had been all but annihilated."

He regards the operation as serious. To escape the criticism of perhaps having hastened death, and "because from the operation no small emolument may be derived," he advises that the patient's friends should be told of the desperate nature of the case.

A longitudinal mark was to be made with ink down the middle line of the neck and a cross mark at the point of the tracheal incision, scarcely the breadth of a thumb below the lower border of the larynx.

Desault was the first to perform the operation of laryngotomy—or, as we would now call it, laryngofissure—by splitting the thyroid cartilage in an individual in whom a foreign body had become impacted in the larynx. In 1768 Pellatan recorded a case in which he had performed laryngotomy for the removal of a foreign body lodged in the upper orifice of the oesophagus.

That intralaryngeal growths were diagnosed and even removed in pre-laryngoscopic days must appeal to us to-day as truly a remarkable feat, yet early in the seventeenth century we find Marcellus Donatus² referring to laryngeal growths, which he describes as warts in the throat. In 1817 Chesman of New York published the record of a case of papilloma of the vocal cords dying without relief. In 1837 Trousseau and Belloc could only report from literature and from their own experience 7 cases. Ehrmann, in 1850, recorded 31 cases of laryngeal growths, including 2 cases of his own. Horace Green in 1852³ records the removal of a laryngeal polyp from a child of 11, which he could see by forcibly depressing the tongue—thus anticipating Kirsch's antoscopy of the larynx.

Middeldorpf⁴ in 1853 removed a polyp, springing apparently from the upper part of the larynx, by means of an incandescence platinum wire loop, and cited 64 cases of laryngeal polypi previous to his own case.

To the student of laryngology the various steps leading up to the discovery of the modern laryngoscope are full of interest. In 1607 Bozzini invented a double cannula with a mirror placed at such an angle that the image of the part seen through one compartment was reflected back to the observer's eye through the other compartment, the source of illumination being a wax candle with a reflector behind.

Cagniard de la Tour in 1825, and Seun in 1827, made attempts with a double series of mirrors to practise antoscopy of the larynx.

In 1829 Benj. Babington presented to the Hunterian Society an oblong piece of glass set in silver wire with a long shank. The reflecting portion of the mirror was to be held against the palate while the tongue was held down by a spatula.

Liston, in 1837, taught that a view of the larynx could be had by introducing such a glass as is used by dentists well back into the fauces and keeping the reflecting surface, previously warmed by dipping in hot water, turned downwards.

In 1838 Baumes exhibited at the Medical Society of Lyons a mirror the size of a two franc piece, which he found useful in examining the post-nasal space and the larynx.

Avery, in 1844, was the first to employ a reflecting forehead mirror with lamp attached, employing a speculum similar to Bozzini's, except that it possessed only one compartment

By general consent, however, Manuel Garcia is considered the real father of laryngoscopy. In his original communication read before the Royal Society of London⁸ emphasizing the practical importance of studying the interior of the voice box, the following sentences occur:

"The pages which follow are intended to describe some observations made in the interior of the larynx during the act of singing. The method which I have adopted is very simple. It consists in placing a little mirror fixed on a long handle suitably bent in the throat of the person experimented on against the soft palate and uvula. The party ought to turn himself towards the sun so that the luminous rays falling on the little mirror may be reflected in the larynx. If the observer experiment upon himself he ought by means of a second mirror to receive the rays of the sun and direct them on the mirror which is placed against the uvula."

Many years later, speaking before the Subsection of Laryngology at the Seventh International Congress in London in 1881, he thus describes his epoch-making discovery:

"One September day in 1852 I was strolling in the Palais Royal preoccupied with the ever-recurring wish so often repressed as unreasonable when suddenly I saw the two mirrors of the laryngoscope in their respective positions as if actually present before my eyes. I asking was this the failures of the London Exhibition of 1851. I bought it for six francs. Having obtained also a hand-mirror I returned home at once impatient to begin my experiments. I placed against the uvula the little mirror (which I had heated in warm water and carefully dried) then flashing upon its surface with a hand-mirror a ray of sunlight I saw at once to my great joy the glottis wide open before me and so fully exposed that I could perceive a portion of the trachea. When my excitement had somewhat subsided I began to examine what was passing before my eyes. The manner in which the glottis silently opened and shut and moved in the act of phonation filled me with wonder."¹⁰

This historical and original pronouncement of Garcia's (for there is no reason to suppose that he was aware of any previous experiments) immediately attracted attention and opposition—not, however, the attention its importance demanded, nor the opposition worthy of an enlightened profession. Thus no less distinguished a scientist than Professor Merkel of Leipzig, writing in the *Anthropophoniik*, 1857, p. 608, says:

"I have not, it is true, been able to obtain Garcia's original observations, and do not know therefore how he proceeded in these alleged experiments, what he has seen and what he has not seen, but I have just grounds to doubt the reality of his observations until I am informed in what manner Garcia has prevented the mirror from becoming dimmed and how he draws forward the epiglottis, which to a great extent hides the glottis from the eye."

As Dean Swift very truly, however, observes: "When a true genius appears in the world you may know him by this sign—that all the asses are in confederacy against him."

Ludwig Türck in 1857, unaware of Garcia's observations, was working in Vienna with a small mirror investigating diseases of the larynx,¹¹ but he was anticipated in publication by Czermack, in a paper which appeared in the *Wiener medizinische Wochenschrift* in March, 1858, entitled "Über den Kehlkopfspiegel." In this paper a large perforated concave mirror was recommended for reflecting either sunlight or artificial light, which in the same year Semeleder adapted to a spectacle frame.

Both Czermack and Türck published books upon diseases of the throat in 1859 and 1860, the publications appearing in French, as both authors had journeyed to Paris—Türck to persuade the savants of the Académie de Médecine that he was the pioneer, Czermack to persuade them that Türck was an impostor, so hot and furious had the contest for priority become.

In 1863 Tobold published in Berlin his *Anleitung zur Laryngoscopie*, and in the same year Louis Elsberg his paper on the laryngoscope and laryngoscopic technique.

To our own countryman, the late Sir Morell Mackenzie, belongs much of the credit of familiarizing the profession with the importance of the laryngoscope, both as a means of accurately diagnosing disease and as a practical aid to treatment. In 1859 he visited Czermack in Vienna, and was present during the acrimonious and none too dignified controversy between Czermack and Türck on the question of priority; in 1863 he was awarded the Jacksonian prize of the Royal College of Surgeons for his essay on "The Pathology and Treatment of Laryngeal Disease." In 1880 Morell Mackenzie published his monumental work, *Diseases of the Throat and Nose*, a book renowned throughout the world for

its erudition, its extraordinary accuracy, and its breadth of knowledge.

The first intralaryngeal operation by the indirect method under the guidance of the laryngeal mirror was performed by Lowin on July 20th, 1860; the second in November, 1861. In a communication to the *Allgemeine medizinische Central Zeitung*, October 12th, 1861, he remarks that intralaryngeal growths are present in from 5 to 6 per cent. of all laryngeal cases, and describes 7 cases he had operated upon himself—3 by cutting operations, 4 by the application of caustics. He therefore anticipated Von Bruns, who, however, as a rule gets the credit, but whose first case was not published until 1862 ("Die erste Ausrottung eines Polypen in den Kehlkopfhöhle," Tübingen, 1862).

In 1866 Elsberg published the first description of the microscopic appearances of laryngeal papillomata.

In 1867 J. Solis Cohen¹² reported the intralaryngeal removal of a laryngeal polyp. So rapid were the strides in laryngological practice that in 1871 Morell Mackenzie published the records of 100 cases in his paper "On Growths in the Larynx," for the first time classifying them as papillomata, fibromata, fibro-cellular or mucous polypi, myxomata, spindle-celled sarcomata, cystic tumours, adenomata, and angiomas.

To our American confrères, past and present, much credit is due, not only for pioneer work, but also for the persistent way they have kept the laryngological flag flying.

In 1817 Dr. Chiesman of New York published a book upon *Growths and Tumours of the Throat*, followed a few years later by Horace Green's work upon the direct treatment of affections of the larynx and trachea, a work which, however, met with furious opposition and almost ridicule. Much the same kind of opposition was also meted out to Dr. O'Dwyer when he introduced his method of intubating the larynx.

The first laryngoscope imported into America was received from Vienna by Dr. Krackowizer in 1858. In 1871 Dr. Elsberg established the first clinic in America devoted exclusively to diseases of the nose and throat, and in 1873 the first laryngological society ever established was started in New York. This society, the New York Laryngological Society, was, however, gradually dissolved, and was incorporated as a section of the Academy of Medicine in 1885.

In 1878 the American Laryngological Association was established; its first meeting was held in 1879 in Buffalo, under the presidency of Dr. Louis Elsberg.

Papers dealing with laryngological subjects were first published in general medical journals and then in otological journals, more especially in the *Archiv für Ohrenheilkunde*, founded in 1864 in Vienna, and in the *Monatsschrift für Ohrenheilkunde*, founded by Voltolini in Berlin in 1866.

In 1874 the *Annales des maladies de l'oreille et du larynx* were published, and in 1880 the *American Archives of Laryngology*. In 1881 the *Archivi Italiani* appeared, and in 1884 Semon's *Centralblatt für Laryngologie*. In 1887 the Spanish journal, the *Revista de Laryngologia*, and in England the *Journal of Laryngology*, edited in the first instance by the late Sir Morell Mackenzie and the late Norris Wolfenden, appeared almost simultaneously. In 1890 the first number of the *Laryngoscope* saw the light of day, and in 1893 the first volume of *Fraenkel's Archives*, truly a "magnum opus."

The driving force behind laryngology was rewarded in 1895 by Kirstein's discovery of antoscopy of the air passages,¹³ which paved the way to the more elaborate and ingenious methods of Killian and Chevalier Jackson, by means of which with snitabily illuminated rigid tubes practically the whole of the respiratory tree can now be brought under inspection, either by direct endoscopy or by suspension laryngoscopy.

Closely allied with laryngology, not only on historical but also on practical grounds, is the art of oesophagoscopy, which followed very shortly after the discovery of the laryngoscope.

Waldenburg was the first to succeed in introducing a short tubular mirror 14 cm. long into the mouth of the oesophagus. To this instrument Störk added a lobster-tail articulation to facilitate introduction. Following this he introduced long rigid tubes, and thus succeeded in realizing the art of direct oesophagoscopy. In the early eighties Morell Mackenzie, and after him Lowe, used a skeleton oesophagoscope with indirect illumination, but without much practical result.

The Leiter-Nietze oesophagoscope, with an internal lamp and system of prisms, followed the indirect method.

Kussmaul in 1868 described the successful examination of the normal and diseased oesophagus, using Desmoureaux's apparatus for illumination. These experiments were confined

by Müller, and yielded the practical result that a rigid tube 13 mm. in thickness may be introduced into the oesophagus of all normally constituted persons. Von Mikulicz deserves the credit of really laying oesophagoscopy upon sure foundations, the problem of illumination having been advanced by Leiter, Casper, Brünings, Kirstein, and Guisez.

That laryngology has played and is playing an important part in relation to general medicine must, I think, be obvious to any serious student of the subject. Just as a knowledge of ophthalmology is of inestimable service in interpreting the many problems associated with the diagnosis of local diseases of the eye and with unravelling the intricacies of certain affections of the central nervous system and other systemic diseases, so also is a knowledge of the clinical appearances of the interior of the larynx as revealed by laryngoscopy of equal value in the interpretation of many pathological lesions, both local and general.

To be able to bring under actual ocular inspection the commencing stages of such diseases as tuberculosis of the upper air passages, the various types of intralaryngeal paralysis originating as the result of morbid affections of the central and peripheral nervous systems, both organic and inorganic, the stenosis due to mediastinal growths, to enlargement of the lobe of the thyroid gland, or to aneurysmal dilatation of the aorta, is surely knowledge worth having.

The physician who to-day is unable to use his laryngoscope and to interpret the clinical pictures brought under his very eye is like the captain of a ship without his chart. True, he may bring his vessel into port, but how much better his chances of doing so would be were the rocks and the quicksands charted in his mind's eye. How often even to-day are the early stages of intrinsic malignant disease of the larynx missed either from a totally inadequate examination, or, what is perhaps as frequent, from no examination at all, and at a time when, literally speaking, cancer of the larynx may be regarded as a curable affection! In the light of our present knowledge the responsibility of the physician or surgeon who looks on, without looking in, at a case of persistent hoarseness is great—is, in fact, criminal. No man of any intelligence can to-day with any justice, considering the enormous strides of human knowledge, decry specialism in any walk of life. The very progress of the art of medicine, in the broadest sense of the term, is due to the fact that the great pioneers of the past have been men who have realized that it is better to thoroughly grasp a knowledge of one part of the human frame than to dabble with its entirety. Critics are fond of saying that the surgeon-specialist is prone to overestimate the value of local treatment, to ignore those general constitutional causes which underlie disease, and to look at pathological processes merely through the mirror of his own speciality, oblivious that the fault is often with the generalist who, neglecting or ignoring the local origin of disease, quite ineffectively treats the patient by drugs for a something which might easily have been recognized and treated successfully had he possessed the knowledge and the necessary *tactus cruditus*.

Work of much scientific and clinical value has been done by the combined efforts of physicians, surgeons, and laryngologists, as will be seen by a study of the innervation of the larynx and of laryngeal paralysis. In 1890 Semon, in association with Horsley, pointed out the greater proclivity of the abductor fibrils of the vocal cords to paralysis—a fact confirmed by the experimental researches of Onodi and Kissien in animals, thus establishing what is now known as "Semon's law." In central and peripheral lesions of the motor laryngeal nerves the abductors only suffer, or at least do so earlier and to a greater extent than the adductors, with the important corollary that laryngeal paralysis which involves the abductors (sometimes in association with the adductors) is due to organic disease, while motor paresis of the adductors is in the great majority of cases functional. With the late Sir Henry Butlin he revived the operation of thyrotomy, now generally called laryngo-fissure, for the removal of intrinsic malignant disease of the larynx—an operation which had fallen into disrepute owing to a former unfortunate selection of cases for its performance, to-day an operation which in skilful hands gives as good, if not even better, results than operations for malignancy in almost any other region of the human body. To cite but one more instance, consider the enormous strides made by the laryngologist in the local treatment of that most painful and distressing of all laryngeal ailments—laryngeal tuberculosis—by the institution of the silence cure, galvano-caustic puncture of foci of tuberculous oedema, and the curetting of laryngeal ulcerations.

Does laryngology occupy the position in the medical curriculum which its importance and its utility demand? I say without hesitation that it does not, and that until it is made a subject of compulsory study it never will. To burden the already overburdened medical student with yet another compulsory class appears almost criminal; yet, on the other hand, it is the business of the university or the teaching school to turn out its alumni equipped and in full harness.

It is difficult to persuade the student that a course of study which is not compulsory is of real importance to him in after-life. When we realize, however, how the State is investing public bodies under its control with ever-increasing powers in relation to the treatment of ear, nose, and throat diseases, in school clinics, welfare departments, and tuberculosis centres; when we realize what a large number of children owe their physical defects and backward development to the presence of diseases of the throat and ear; and when we also realize how much can be done to relieve them of their disabilities, it is the duty of those in charge of these special clinics to urge and to continue to urge upon the powers that be the necessity of insisting that every student shall have before he quits the portals of his university at least a reasonable theoretical and practical knowledge of laryngology and otology.

The Scottish universities, ever to the fore in educational facilities, now make the study of laryngology and otology compulsory. Each student has to attend the throat and ear department of his hospital for one term, to receive both systematic and clinical instruction. Examination is not demanded in Glasgow, but is compulsory in the other three universities, while in Edinburgh the student has to obtain 50 per cent. in this special examination before he is admitted to his final professional.

The time has surely come when, in the interests of the general public, the English universities and qualifying bodies should do likewise. Much encouragement to the study of laryngology and otology would also be afforded were there more clinical appointments in the special departments of our general hospitals, and were facilities made to hold such appointments for considerably longer periods than is possible at present; also were some special degree in laryngology and otology instituted to signalize the fact that its possessor had had a thoroughly good training in the special department which was to be his life's work.

With this end in view the Council of the Laryngological Section of the Royal Society of Medicine has recently appointed a committee, of which I have the honour to be a member, to draw up a memorandum to be presented to the Royal Colleges of Physicians and Surgeons, in which memorandum there are *inter alia* the following recommendations:

1. That attendance at the hospital throat and ear clinic be compulsory.
2. That no student be allowed to proceed to his final examination unless he can produce documentary evidence that he has attended (and has been signed up) a practical course upon diseases of the throat, nose, and ear.
3. That the qualifying examination in the diagnosis and treatment of the more common diseases of the throat, nose, and ear, and in the use of the more ordinary instruments, be both practical and oral.
4. That the examination be conducted by recognized laryngologists and otologists.

I would fain see the status of the teacher of laryngology be that of a professor and not of a lecturer.

The question of emolument attached to a professorship does not need to enter the scheme at all—it is the status that is wanted, the recognition and accentuation of the importance of the subject.

The ever-widening path of human progress demands that these changes should come. As the great surgeon-orator, the late Sir James Paget, in speaking of the future of pathology, said, "Where, then, are we to stop? I do not know more than this, that we must not stop where we are; we must go on and on, and we may be sure that they who work to find the truth will not work in vain, sure that with true work true good will come."

That these changes, these steps to the realization of a higher standard of efficiency in the medical profession, will come I feel sure; that they may come quickly is my earnest desire, confident as I am that our path of duty lies just as much in the prevention as in the cure of disease, in the early recognition and successful handling of the many ailments which threaten our sense organs—organs very responsive to intelligent treatment, but which,

when damaged, seriously hamper individual activity and utility, and collectively tend to undermine our national vigour, prosperity, and well-being.

THE NATURE AND SIGNIFICANCE OF HEART SYMPTOMS.

BY

ST. JAMES MACKENZIE, M.D., F.R.C.P., F.R.S.

(From the Institute for Clinical Research, St. Andrews.)

II. THE REFLEX PROCESS AND THE HEART BEAT.

As disease is only recognized by the symptoms it produces, a knowledge of symptoms is a necessary preliminary to an intelligent investigation of disease. This knowledge of symptoms is necessary not only to the diagnosis of a patient's complaint but for a prognosis and a rational treatment. The symptoms of disease even in one sick individual may be numerous and varied, so that it is impossible to study every symptom with that care and insight which are necessary for understanding its use in the practice of medicine. The search for symptoms by new methods leads to the discovery of many, but the result is often but to add to the mass of details which obscure the problems of disease, and some other method of investigation is urgently needed.

Phenomena in nature, however numerous and varied, are subject to definite laws. Progress in every branch of knowledge which deals with these phenomena is hampered until these laws are discovered. The symptoms of disease are natural phenomena, and the vital processes concerned in their production are certain to be few in number, and the nature of symptoms will not be understood until these vital processes are discovered.

Recognizing that a knowledge of symptoms was the first step in the investigation of disease, the staff of the St. Andrews Institute for Clinical Research began their work by a search for the laws governing the production of symptoms.

In the course of this inquiry it was found that a great mass of symptoms were produced by disturbance of a single vital process—that which includes what is known as reflexes. The term "reflex" had been restricted to a few manifestations of a vital process, so that its affinity to other manifestations had not been recognized.

Though reflexes had received much attention, yet the manner in which they were modified by disease had received little attention. We therefore have devoted a good deal of study to the process as it concerns different organs, and in this article I deal with the light which the recognition of this process has thrown upon the mechanism of the heart beat.

The Nature of the Reflex Process.

We tried to look at the reflex acts from the point of view of the vital process. We analysed the parts concerned in a reflex arc. The arc consists of cells that are capable of stimulation connected in some way with cells that are capable of producing an effect. In some instances we can recognize the stimulus and the cells stimulated, but as a rule we can only recognize the effect. In the vast majority of reflexes we can only infer or guess at the nature of the stimulus, while of the manner of conduction from the cells stimulated (receptor cells) to the cells activated (effector cells) we have only the vaguest notion.

The parts concerned in a reflex act are the stimulus, the cells receiving the stimulus, the cells concerned in the conduction of the stimulus, and the cells which respond and produce an effect.

It will be seen that this process includes a great variety of responses or manifestations widely different in character and appearance, as contraction of muscle, secretion of glands, sensations, etc. For this complicated process we required a term, and we attempted to get one which would be compre-

hensive, but on consideration we found that no term could convey so much of the process as the term "reflex." To avoid confusion we tried to give a clear description of what was meant by the term. The meaning we attach to the term "reflex" is that vital process by which a stimulus passes from one tissue or organ to another, resulting in a response. The nature of the response depends on the function of the organ stimulated.

In this definition of the reflex process the manner in which the stimulus is conveyed from the receptor cells to the effector cells is not mentioned. Hitherto it has been assumed to be by nerves, but nerves are not necessary to the process, for other tissues may convey the stimulus, as will be realized when the evolution of the nervous system and the movements of the heart are described.

The Origin and Evolution of the Reflex Process.

The test of a new conception is the light that it throws upon obscure problems. The application of the theory of disturbed reflexes led to an examination of the mechanism of the heart beat—a mechanism which depends upon this vital process which we call reflex, and it fulfils the test of a true conception, as it presents the whole subject of the heart beat and its disorders in a new and better light. It also provides an interpretation of many facts which had either been misunderstood or overlooked, and gives a guide in which direction to look for other facts.

The nature of the process we call a reflex can be gathered by the description given in Bayliss's *Principles of General Physiology* of the evolution of the nervous system. This system begins in the conduction of a stimulus in the lowest multicellular organisms, where the communication passes from cell to cell without any intermediate mechanism. The next stage may be seen in the sea anemone, where projections of the ectodermic cells are connected with muscle fibres. The next stage may be considered to be that when a nerve cell is interposed the stimulus arising in one cell (the receptor or A part of the reflex) passes to a nerve cell (the centre or B part of the reflex) which is connected with the organ which gives the response (the effector or C part of the reflex). This stage, simple at first, as in the earthworm, becomes extremely complicated, especially in the central or B part of the reflex, which is situated in the central nervous system, where the stimuli are rearranged and guided into the paths for the production of their effects. The portion of the reflex in the central nervous system is that generally spoken of as "centres"—as the centre for vomiting, for respiration, for micturition, etc.

It will be seen that this description of the evolution of one part of the nervous system deals with the passage of a stimulus from one tissue to another, corresponding with our conception of a reflex.

The Reflex Process and the Movements of the Heart.

In the different rhythms of the heart we find variations in the reflex process, corresponding in a curious manner with Bayliss's description of the evolution of the nervous system. In certain abnormal conditions the muscle cells of the auricle and ventricle may contract independently of the control of the normal mechanism. The contraction of one cell stimulates its neighbour to contraction, and hence we get that remarkable condition called fibrillation. In this condition the muscle wall, though as a whole it stands still, is seen to be in continuous movement on account of the inharmonious contractions of the individual muscle cells. No sooner does one cell contract than it is again stimulated to contraction by its neighbour—that is to say, the stimulus evoked by one cell passes directly to another, in the manner described as the first stage in the evolution of the nervous system.

The stimulus for contraction of the ventricle passes from the auricle to the ventricle along the auriculo-ventricular bundle. (See Fig. A.) If this bundle or a portion destroyed by disease the ventricle no longer responds to the stimulus from the auricle. The ventricle, however, does contract at a slower and different rate from the auricle. There is good reason for assuming that the stimulus arises in the remains of the bundle and passes to the ventricle by the Purkinje cells. Thus we have an illustration of the reflex process where the stimulus arises in the Purkinje cells and is conveyed by them to the effector organ—that is, to the muscle cells of the ventricle.

The process is similar, though a little more complex, when the stimulus arises in the auriculo-ventricular node or in the auricle. The stimulus for contraction arises normally in the

sino-auricular node, passes directly to the auricle, causing it to contract, is taken up by the cells of the auriculo-ventricular node, which reproduce the stimulus and send it by the bundle to the ventricle, thus giving rise to that regular sequence of auricular and ventricular contractions which facilitates the work of the heart.

It is to be observed that in this description of the conduction of the stimulus the stimulus is not conveyed by nerve fibres but by the Purkinje cells, the stimulus passing from cell to cell. Comparisons have been made of the rate of conduction along nerve fibres with that along the auriculo-ventricular bundle, but the conditions are not comparable because the nerve fibre is a continuation of one cell, while in the bundle the stimulus passes through a great number of cells. Above the sino-auricular node, and modifying its activities, are the vagus and sympathetic nerves. It is through these that the heart's action is reflexly affected by agents outside the heart. We thus see that the heart's rate and rhythm, both normal and abnormal, are governed by variations of the same vital process. How the recognition of this fact leads to a fuller understanding of the variation of the heart beat and the factors engaged in modifying it will be seen in the account which follows.

The Practical Application of the Reflex View of the Mechanism of the Heart Beat.

This description of the mechanism of the heart beat may appear to be of the nature of an academic disquisition and of little practical value. On the contrary, this appreciation of the factors concerned is essential to the understanding of the signs and symptoms of disease and of the action of remedies. Indeed, the reason of the backward state of cardiology and of our knowledge of the action of remedies is due to the failure to grasp the principles involved in this aspect of the subject.

In the last article it was shown that there were two kinds of tissue concerned in the movements of the heart: (1) that concerned in the production and the conduction of the stimulus which regulates the contraction of the chambers (the conducting system); we may also call it, the reflex system (Fig. A); (2) that concerned in the contraction of the chamber—the muscle cells of auricles and ventricles (the contracting system).

These two systems are quite distinct in function, and the manifestations in health and disease of the one system are quite distinct from the other, and the kinds of information yielded by the symptoms of the two systems are also quite distinct.

The conducting system, with the sympathetic and vagus nerves, is concerned with the regulation of the rate and rhythm of the heart's contraction. The agents of disease readily affect some parts of this system, and in consequence we get the symptoms which are peculiar to this system—that is, variations in the rate and rhythm.

The contracting system, on the other hand, is concerned with the output of blood from the heart—that is, with maintaining the functional efficiency of the heart. When the heart begins to fail—that is to say, when its functional efficiency becomes impaired—the symptoms belong to quite a different category from that of the conducting system.

If this distinction is kept in mind it will be realized that attempts to find out the functional efficiency of the heart by observing the variations in the rate and rhythm of the heart are bound to fail, for the simple reason that information of a kind is sought from a source that cannot yield it.

The introduction of auscultation was followed by long and careful research to find out the cause of murmurs. The excellent results were vitiated by the failure to recognize the kind of information which had been obtained. It was thought that the functional efficiency of the heart could be ascertained from the modified sounds of the heart. To-day we find the modified sounds used as a guide in treatment and prognosis—a kind of knowledge they are incapable of supplying.

The interpretation of variations in the rate and rhythm of the heart has been misapplied in the same way; for the kind

of knowledge they reveal has not been understood. That the functional efficiency of the heart depends on the integrity of the heart muscle is such a commonplace that it seems unnecessary to mention it; but we find that the information of functional inefficiency or heart failure is sought for in signs which have nothing to do with the functional efficiency of the heart muscle, while the signs peculiar to the inefficiency of the heart muscle are overlooked.

It is true that certain murmurs may indicate valves so damaged that they impede the work of the heart muscle. But it must be realized that they only oppose a hindrance to the contracting system, and it is the exhaustion of the contracting system that produces the symptoms of heart failure—that is to say, while heart murmurs may indicate conditions that may lead to heart failure, they do not of themselves give the signs of heart failure. In the same way the conducting or reflex system may occasionally give certain signs which we associate with heart failure, or which may lead to heart failure (as an excessive increased or diminished frequency), but these are not the signs of heart failure.

The variations of rate in response to effort, which are so often taken as evidences of functional efficiency, are thus seen to be due merely to a susceptibility to stimulation of some part of the conducting or reflex system which may have nothing to do with the heart's state of efficiency. Thus as the signs of damaged valves give one kind of evidence, so does the manifestation produced by the conducting or reflex system give another kind, and the signs of the contracting system give information distinct from the other two.

The Kind of Information Yielded by Disturbance of Rate and Rhythm (the Reflex or Conducting System of the Heart).

The phenomena produced by disturbance of the reflex system of the heart can best be described by recognizing two different kinds of mechanism which regulate the heart beat—(1) when the rhythm starts at the sino-auricular node (the normal rhythm), and (2) when the heart's contraction starts at some other place in the heart (abnormal rhythm). I propose to deal very briefly with the evidences, merely showing how the recognition of the disturbances throws light of a valuable kind on diseased states and on the effects of remedies. The knowledge acquired so far is limited, but such as it is it shows the lines on which more valuable knowledge can be acquired.

The normal heart beat starts at the sino-auricular node, where the stimulus for contraction is produced. The stimulus passes to the auricle and ventricle in the manner already described. It will thus be seen that in the normal heart beat the variations in rate and rhythm of the pulse are entirely dependent on the sino-auricular node. The cells of the sino-auricular node, after the discharge of a stimulus, are exhausted and remain quiescent for a short period, during which they recover from the exhaustion. As this period of recovery lengthens they become more and more susceptible to stimulation, until they again discharge their stimulus. What it is that excites them to "go off" is not quite clear, but certain agents have the power of increasing or diminishing their susceptibility—as heat, which causes an increase in the rate, or cold, which causes a decrease. It is possible also that agents circulating in the blood may affect the cells in a similar fashion; certain agents like alcohol seem to increase their sensibility, while others like digitalis may decrease it. In like manner the agents of disease may act, by the increase in temperature or by the toxic products.

The sino-auricular node has inherently a pace which is modified by certain circumstances. It is under the domination of the nervous system by means of the vagus and sympathetic nerves. The vagus maintains such a control over the sino-auricular node in health that it is never free from its inhibitory influence. A relaxation of vagal activity is followed by an increased rate of the pulse. The sympathetic acts in the opposite manner to the vagus, and an increase in its activity leads to an increase in the rate of the

FIG. A.—Diagram representing the two main systems concerned in the heart beat. (1) The conducting system, represented by the sino-auricular node (S.A.N.) and the auriculo-ventricular node (A.V.N.) and bundle (A.V.B.). In both auricles and ventricles are also Purkinje fibres which belong to this system, represented by the scattered cells (r) in the auricle. The vagus (vag.) and sympathetic (sy.) also belong to this system. (2) The contracting system, represented by the muscle cells of the auricle (A) and ventricle (V).

heart. Here is where the great difficulty in interpreting variations of rate comes in. The sino-auricular node without vagus influence would cause an increase in the heart's rate. When, then, we find an increase in rate, we have to ask whether it is due to the sino-auricular node being freed from vagal activity, or to an increase of the sympathetic influence, or to a direct effect of some agent (temperature, toxins, drugs) on the sino-auricular node itself. These are the types of questions that require settling before we can understand the action of remedies or the symptoms of disease.

We know already a little, but that little indicates that there is much more to be known. We know, for instance, that the increased heart rate that follows the administration of atropine is due to a suspension of vagal activity, and that the increase in rate is different from that which follows a rise of temperature or effort, or the administration of alcohol. It is also known that digitalis may have a definite effect on the vagus, stimulating it and so restraining the activity of the sino-auricular node.

Varied as are the effects of drugs diseased states have effects as distinctive, for agents of disease affect the reflex system in diverse places and diverse ways, and it is by the recognition of these diverse modifications that the different diseased states can be recognized. We know that the reaction is different in pneumonia from that in typhoid fever, and these again from that in rheumatic fever. During some infections the conducting system may be affected, as shown by the temporary presence of partial heart-block.

But there is more than that, for the agent of disease modifies or counteracts the action of drugs. Thus, though in the normal heart atropine increases the rate, yet in certain diseased states it may slow the heart's rate. In some forms of disease digitalis will slow the heart rate, in other diseased states it is without effect. The recognition of these facts explains the reason of the confusion which reigns in the therapeutic field. A great deal of work has been done in testing the action of drugs on the healthy heart, but it has not been realized that the diseased condition modifies the effects of the drug. When it is realized that it is chiefly on some part of the reflex process that most drugs act the importance of a better understanding of this process will become apparent, all the more so when it is further realized that it is also by the modification of some parts of this process that many symptoms of disease arise. If these points are grasped it will be seen that in the sick man the agents of disease have affected the parts on which the drugs act, and therefore we can state as a principle which must be recognized in the investigation of the action of drugs that *the effect of a remedy is modified according to the nature of the disease*. It is the neglect of this principle which keeps therapeutics in the state of confusion in which they are at present.

Other reactions have to be considered. R. M. Wilson has lately drawn attention to a factor that has not been recognized—the secondary reaction to a stimulus. In a balanced reflex, when an act is regulated by two nerves acting the one in opposition to the other, the excitation of one is accompanied by the diminished action of the other. When the excitation ceases the nerve whose activity was diminished may greatly increase its activity. Thus a temporary slowing of the heart by stimulation of the vagus may be followed by a great increase in the rate of the heart by secondary reaction of the sympathetic (a reflex stimulation of the sympathetic by the vagus).

Abnormal Rhythms.

If the understanding of the reflex system is of importance with the normal rhythm, it is evident that with an abnormal rhythm it is of still greater importance. The various places where the heart beat may start are different in structure and in function from that of the normal starting place (the sino-auricular node), and in consequence the effects upon the ventricles are different. This was so fully dealt with in the previous article that I need not dwell upon it here, save to refer to the differences which follow effort in the cases, say, of the normal rhythm, auricular fibrillation, and heart-block, and to the difference of the effect of drugs like digitalis. Moreover, the fact that the stimulus which is produced by the cells of the contracting system—as in auricular fibrillation, flutter, and the idio-ventricular rhythm—is different from that which arises in the cells of the conducting system calls for a reconsideration of the mechanism of these abnormal rhythms and of their relation to the various agencies (effort, drugs, heat, toxins of disease) which act upon them.

SUMMARY.

1. The mechanism concerned in regulating the heart beat belongs to the vital process included under the term "reflex."
2. The cells taking part in this mechanism belong to two groups: an extrinsic, connected to the nervous system by the vagus and sympathetic nerves, and an intrinsic, which includes the sino-auricular and auriculo-ventricular nodes, and the Purkinje cells in the bundle and auricles and ventricles.
3. Agents of disease (toxins) which modify the rate and rhythm act on different parts of this mechanism, and certain disease agents produce characteristic effects.
4. Drugs that influence the rate and rhythm of the heart act in the same way, some of them also producing characteristic effects.
5. As toxins act on the same parts as drugs the effects of drugs will be modified by the effects of the toxins.
6. Before the effects of a remedy can be investigated it is necessary to know if the toxins have not already produced an effect which will interfere with the action of the remedy.
7. The kind of knowledge which disturbances of the reflex process reveals is limited to the variations in rate and rhythm, and they give no information regarding the functional efficiency of the heart.

THE PEPTIC ULCER.

WITH A REVIEW OF TWELVE MONTHS' SURGICAL TREATMENT (1921).

BY

K. W. MONSARRAT, M.B., C.M., F.R.C.S. EDIN.,
LECTURER ON CLINICAL AND OPERATIVE SURGERY, UNIVERSITY OF
LIVERPOOL; SURGEON, NORTHERN HOSPITAL, LIVERPOOL.

To obtain control over any disease it is necessary to possess means which can be safely employed to eradicate it when established, and a knowledge of its etiology such as will enable us to prevent its occurrence or recurrence. Surgical experience has made a very substantial contribution towards the mastery of peptic ulcer. It has contrived means of dealing radically with ulcers which are safe, at least in practised hands and when employed with discrimination. In the course of arriving at its technique it has thrown a great deal of light on the conditions which determine peptic ulceration, and which, if undisturbed, will tend to its recurrence. I will argue later that with the assistance of radiology it has now actually reached an understanding of the immediate cause of ulcer, and has determined, although not exhaustively, the ulterior causes.

Among the contributions which radiology has made to medicine none is more brilliant than that which it has made to the diagnosis of gastric disorders. Without its assistance the diagnosis of ulcer uncomplicated by penetration or haemorrhage or stenosis was only a matter of suspicion. Now suspicion can be put to a test in which the margin of error is, in my experience, extremely small. I wish to express my gratitude to my colleagues, Dr. Oram and Dr. Mather, to whom I owe the reports on the cases which I propose to review.

Of these cases, 48 in number, on whom I operated in 1921, 41 were men, 7 women. In 34 instances the ulceration was gastric, in 8 duodenal, and in 6 jejunal. These figures do not include other simple disorders of the stomach, such as those which depend on adhesions or those due to pylorospasm without ulcer, but I wish to refer shortly to these two classes.

Adhesions Involving the Stomach.

One is impressed with the gross disturbance of function and the stimulation of visceral disease which may be caused by such adhesions. I have opened the abdomen on four occasions during the year in cases of this kind, the patient in each case being incapable of following any occupation. In all four the adhesions were chiefly between the stomach and the anterior abdominal wall deep to an operation scar. According to the histories obtained the earlier operation had been as follows:

1. For gastric ulcer (evidence of operation on pylorus).
2. For perforated gastric ulcer (suture).
3. For gastric ulcer (gastro-enterostomy).
4. For perforated duodenal ulcer (suture).

Infection is the cause of such adhesions. When formed between the stomach and the abdominal wall they may cause

pain of severe intensity associated with the period of digestive movement, and pain is also characteristically complained of when exercise is taken. In dealing with them the omentum is of service; after separation the whole area concerned is covered by omentum fixed by sutures in whatever directions it may be desirable. The fourth case deserves special notice.

A man aged 46 on whom, at the age of 31, I operated for perforation of a duodenal ulcer. In 1918 I operated again and found no ulcer on the lesser curvature of the stomach; a posterior gastro-enterostomy was then done. In June, 1921, he was again admitted complaining of sharp stabbing pain in the left hypochondrium. I found the gastro-enterostomy opening in good order, the ulcer of the lesser curvature healed, and no ulceration elsewhere. The stomach was, however, attached to the anterior abdominal parietes, and also to the liver. These adhesions were dealt with as detailed above, and when I saw him six months later he told me that he had been free of all pain or discomfort.

Pyloric Spasm.

Cases of pyloric spasm and pyloric hypertrophy do not strictly belong to my subject. In four cases seen during the year ulcer was suspected either on the ground of clinical signs or of x-ray report, or of both. In all four a pyloric incision was made to demonstrate definitely whether ulcer was present or not. The operation was completed as a pyloroplasty. Relief of symptoms and increase of weight have followed in each case. Ulcer was simulated clinically in all four; in two the radiological diagnosis was also ulcer, in one the report said simply "marked delay," and in the fourth the stomach was reported normal in outline and function.

PEPTIC ULCER.

The forty-eight cases of peptic ulcer fall into six groups:

Group 1.—Perforated duodenal ulcer; two cases. Treated by infolding suture, gastro-jejunostomy, and pelvic drainage.

Group 2.—Ulcer of the lesser curvature, treated by ulcer excision alone or by excision and gastro-jejunostomy. This group includes three cases only. For reasons which will be discussed later ulcer excision alone is not a satisfactory operation.

The first case illustrates the disappointing result of this operation, an experience which has been recorded by other surgeons. It was adopted in this case with a view to shortening the operative procedure as much as possible, but other experience has shown me that it is never advisable on this ground and that there are better means of dealing with patients who are much reduced in strength by their disease. In this case, eight months later, I supplemented the ulcer excision by gastro-enterostomy. Gastric pain had persisted and vomiting was frequent. At this second operation, while no ulceration was found, the stomach was seen to be somewhat deformed at the site of the excision and this was apparently the cause of his symptoms. Since the supplementary operation he has done well.

In the second case of the group the ulcer was excised on account of repeated serious haemorrhage. A blood transfusion made operation possible; in the floor of the ulcer was a large vessel showing a perforation temporarily plugged by clot.

In the third case the operation was chosen, as in the first, because of the general condition of the patient did not seem to admit of gastro-enterostomy. Excision was, however, supplemented by gastro-jejunostomy at the same time and from this combination better results are obtained than by excision alone.

Group 3.—Comprises ten cases treated by posterior gastro-enterostomy alone. In six instances the lesion was duodenal ulcer, in three gastric ulcer, in one pyloric stenosis.

Group 4.—Comprises two cases in which the operation was transgastric suture of the ulcer. In one case I had to deal with an ulcer near the cardia in a stomach which lay high up under the diaphragm. The stomach was small and the whole of it lay under the ribs, and the ulcer area was inaccessible except by gastrotomy.

The other case is somewhat remarkable in that both I and another surgeon opened his abdomen, the clinical and radiological diagnosis being ulcer, and found none. Six months after the operation, which I performed and in which adhesions appeared to be the cause of his symptoms, he was readmitted after a massive haemorrhage. I found an ulcer high on the lesser curvature, difficult of access, and also penetrating. It was sutured after gastrotomy.

The clinical result in these two cases has been satisfactory for the time being, but the proceeding is probably not radical enough for a permanent result. The condition of these two patients is, however, surprisingly good, as far as complaint is concerned.

Group 5.—Includes the cases, twenty-five in number, who were treated by partial gastrectomy. In three cases the operation was a "sleeve" resection. In the remainder the operation was what is most commonly described as the

posterior Polya or Reichel operation—that is to say, resection of the stomach from the pylorus to beyond the ulcer-bearing area, closure of the duodenum, and anastomosis of the stomach wound to the jejunum through a mesocolic gap.

Group 6.—This group consists of six cases of jejunal ulcer. In these cases no one procedure is always suitable. The ideal procedure, as carried out in one case, is as follows: The pylorus was divided and the duodenum closed; the stoma was resected and the gastric and jejunal wounds left by this resection were closed. The pyloric half of the stomach was then resected and the stomach wound was anastomosed to a jejunal loop at a point about eighteen inches from the jejunal commencement, the anastomosis being retro-colic. The other procedures were:

- (a) Two cases. Resection of the stoma; gastro-jejunostomy in Y.
- (b) One case. Resection of stoma; end-to-end anastomosis of jejunum.
- (c) Two cases. Resection of stoma; gastric and jejunal wounds closed.

Simple resection of the stoma with closure of the stomach and jejunal wounds is obviously only suitable when no ulcer or stenosis exists elsewhere. If there is ulceration or stenosis in the stomach I think the operation is best completed by resection after the proceeding of Polya, or by a long loop gastro-jejunostomy. I do not like the Y gastro-jejunostomy; it is technically difficult after resection of the stoma, and has the worse fault of giving no safeguard against a reappearance of jejunal ulceration.

Among the forty-eight cases of the several groups there was no mortality, but two cases gave rise to some anxiety.

The first was a difficult case of partial gastrectomy for ulcer toward the cardiac end of the lesser curvature. A cigarette drain was used. On the sixth day there was a definite leakage of gastric secretion; jejunostomy was performed and mouth feeding stopped. The sinus closed in twenty-four days.

The second case was one of sleeve resection for mid-gastric stenosing ulcer. A fortnight after operation he showed abdominal distension which proceeded to complete obstruction on the eighteenth day. A volvulus of the ileum was found and released.

The necessity for operative treatment of peptic ulcer, apart from complication, arises from its resistance to other forms of remedy. The conditions of a peptic ulcer may be said to be three:

1. The ulcer involves the visceral wall alone; it is non-penetrating, non-stenosing.
2. The ulcer is penetrating.
3. The ulcer is stenosing.

Opinions do not differ as to the necessity for operation in the stenosing ulcer; few will expect a favourable result in penetrating ulcer without operation, but there is evidence that many non-penetrating ulcers will heal under general and local medical treatment. Up to the present it is not possible to base such treatment on an etiology that is demonstrated and acknowledged. That peptic digestion plays a definite part in the etiology is admitted, but pathologists are still searching for some antecedent condition rendering the gastric mucous membrane vulnerable to attack by the gastric juice. It is by no means certain that there is any such general antecedent lesion, or, in fact, that there are any causative factors other than an altered gastric secretion and an altered gastric rhythm. Any theory of the causation of this ulcer must explain its incidence in stomach, duodenum, and jejunum. The jejunal ulcer is illuminating. It shows that the normal jejunal wall submitted to the direct action of the gastric juice may suffer destruction. I am aware that many surgeons believe that only a jejunal wall damaged by the presence of a foreign body, such as an unabsorbable suture, is liable to peptic attack. There is undeniable evidence to the contrary, and the six cases here recorded add to it. In one of the cases a fragment of silk was found near the ulcer site, but not actually at the ulcer; in the other five cases there was no such foreign body. It is said that damage done by a clamp may be responsible for the ulcer, but two considerations negative this being a usual factor—the one that jejunal ulcer does not commonly occur at the clamp line, the other that many jejunal ulcers make their appearance long after any possible clamp injury must be presumed to have disappeared. As far as jejunal ulceration is concerned there is evidence that, given a certain chemical state of the gastric secretion, the normal jejunal mucous membrane will succumb to peptic digestion. I submit that the same holds good for the stomach and duodenum, and that if we have regard to the physiology of the gastric secretion, and more particularly to its intimate relations to pancreatic secretion,

the occurrence of gastric, duodenal, and jejunal ulceration, under conditions which disturb these relations, is explained.

The stomach consists of two segments, a fundal segment and a pyloric segment. The chemistry of these two segments may differ materially at any given moment: the fundus is occupied with salivary digestion in the early stages; the gastric secretion poured out from border cells and gland cells accumulates in the pyloric segment, and it is here that peptic digestion takes place. Langley compares the peptic activity in the pyloric segment with that in the fundal segment as 73 to 1. The pylorus is not a closed orifice during normal digestion. Quite early in the process small quantities of gastric juice and food pass into the duodenum, and in the cells of the duodenal mucous membrane the hormone of pancreatic secretion is formed. There is also a regurgitation of pancreatic secretion into the stomach. Rehfuss, using trypsin as an indicator of this regurgitation, has shown that it is regularly associated with normal digestion, and that the trypsin value is high in the presence of low acidities and low when the stomach contents are of high acid concentration. Boldyreff believes that gastric acidity is lowered to an optimum by this passage of pancreatic fluid. However that may be, pancreatic secretion, which on the one hand is evoked by the gastric secretion, on the other hand acts as a regulator of the activity of peptic digestion. There is thus a correlation, diaplasia, between gastric secretion and pancreatic secretion. *This correlation is dependent on an intact pyloric mechanism.* We must not indulge the notion that it is the free acid of the gastric juice which is the noxious agent in producing gastric or duodenal ulcer. Free hydrochloric acid is absolutely innocuous in the concentrations in which it is met with in normal or pathological stomachs. It is merely a rough indicator of peptic activity; in fact, it can hardly be said to be even this, for the ratio of peptic power is not proportional to the acidity. What we can say is that, generally speaking, peptic attack only occurs in an acid medium.

Now we have been shown by the radiologist that in both gastric and duodenal ulcer there are certain departures from the normal in the motor functions of the stomach and the pylorus; that in gastric ulcer the stomach is characteristically hypotonic and retains its contents for an undue length of time; that in duodenal ulcer the stomach is hypertonic, and that there is hurry in emptying. In both cases there are certain departures from the normal in the pyloric mechanism. Hurst says that these motor aberrations are present before ulcer appears and persist after it has ceased to be clinically apparent. In other words, that they are primary, or at any rate precede and are independent of the presence of ulcer. What will be the effect of such aberrations on the correlation of pancreatic and gastric secretion? If the stomach is hypotonic, if there is pyloric spasm and stasis, there will be a failure in the hormone stimulation of pancreatic secretion, and on the other hand a failure in the regurgitation of pancreatic fluid into the stomach. Under such conditions the wall of the organ will be subjected to an unduly prolonged contact with a gastric juice which is unchecked and unregulated by pancreatic regurgitation. The gastric wall suffers damage under these conditions, and the damage may end in ulceration.

If, on the other hand, the stomach is hypertonic, if the pyloric sphincter allows, not the normal intermittent discharge of small quantities of acid peptic fluid into the duodenum, but the early flooding of the duodenum with peptic fluid before pancreatic secretion is active, the duodenal wall is then subjected to gastric juice of unchecked peptic activity. It is therefore in the duodenal wall that we find the ulcerative lesion when the functional aberration is that of hypertonicity and hurry. In an analogous way may be explained the incidence of jejunal ulcer after anastomosis. It occurs when the peptic activity of the gastric juice is high, and when for some reason the pancreatic secretion, which normally checks this activity, defaults.

It would appear, then, that we can find in derangements of the gastro-pancreatic correlation a sufficient explanation of the incidence of peptic ulcer (given a peptic secretion of high activity), and also reasons for its varying site. We have at present incomplete knowledge of the conditions which set up these primary functional disturbances; they themselves do not appear to be dependent on the chemistry of the gastric secretion, for hypersecretion and hyperchlorhydria are usual both in the hypotonic stomach of gastric ulcer and the hypertonic stomach of duodenal ulcer. We do know, however, that visceral disease elsewhere—for example, in the appendix and gall bladder—may be connected with such functional

gastric disorders, and that the latter may disappear after surgical treatment of the focal disease.

In treatment we have regard to three main points:

1. The ulceration itself.
2. The activity, or excessive activity, of the gastric secretion, and the default of the mechanism which normally controls this.
3. The disturbances of motor function which precede and account for both.

Surgical treatment deals with ulcer (1) by methods of removal which leave no embarrassing deformity behind; (2) by anastomosis, which provides a permanent check on the peptic attack of the gastric juice; (3) by removing any focus of disease elsewhere.

All the cases reviewed here had had a lengthy period of medical treatment extending from many months to many years. I am aware that under the term "medical treatment" I include different types of treatment more or less thorough. Very high claims were made by physicians for what I may call the "satisfaction" method, the basis of which is the Lenhartz diet. I do not think that physicians are now satisfied with the permanence of results obtained by this method. That which is in most favour to-day is the "neutralization" treatment identified with the name of Dr. Sippy of Chicago. Dr. Sippy summarizes the claims he makes for this method in the *New Oxford Medicine*, vol. iii, p. 169. They are too long for quotation. I have been unable to find clinical records of a large series of cases treated by this method and followed over long periods afterwards. This is the most satisfactory evidence, and is most valuable if late results are recorded in the patients' own words.

The surgical remedy for duodenal ulcer is posterior gastro-jejunostomy. The anastomosis between stomach and jejunum must measure three inches in its long diameter, and it must encroach on the pyloric segment of the stomach. Some surgeons add to the gastro-jejunostomy an excision of the ulcer, others add occlusion of the pylorus. Failure to obtain permanent relief by gastro-jejunostomy is so exceptional that to add either the one or the other appears to be unnecessary. I have employed occlusion of the pylorus on many occasions; I do not think it has any effect on the result in duodenal ulcer, and I am doubtful whether it is physiologically sound. The activity of pancreatic secretion is likely to be checked if the gastric contents are excluded from the duodenum.

In gastric ulcer healing is most certainly brought about by removal of the ulcer. Can gastro-jejunostomy be relied on to so remedy the stasis in the stomach and the peptic activity of the gastric juice that ulceration will not recur? Certainly ulcer excision alone is not sound, and gastro-enterostomy alone cannot be relied on, and even in combination the results are by no means uniformly good. I may instance a case of ulcer of the lesser curvature for which, some two and a half years ago, I did posterior gastro-jejunostomy. This anastomosis is still anatomically satisfactory, but the ulcer did not heal, and I subsequently excised it. Relief was only temporary. The patient then naturally transferred himself to another surgeon, who removed the pyloric portion of the stomach as far as the anastomosis, and in this pyloric portion was a new ulcer. Yet gastro-enterostomy is a remedy of value even in inveterate gastric ulcer, but it is not the remedy of choice; a more radical procedure is advisable. That more radical operation is partial gastrectomy. The term includes two different procedures, either—

- (a) Sleeve resection with gastro-gastrostomy; or
- (b) Resection of more or less of the stomach, including the ulcer, closure of the duodenum, and anastomosis of the stomach and jejunum.

Sleeve resection I believe to have only a limited field; it is the operation of choice for mid-gastric cicatrized ulcer. In the presence of active ulcer it is open to the same objection as simple ulcer excision, in that it does nothing to modify the chemistry of the gastric secretion.

Partial gastrectomy combined with a gastro-jejunal anastomosis does two things: in the first place, it removes the ulcer and the ulcer-bearing area; in the second place, it renders the stomach incontinent and prevents finally the accumulation of a noxious gastric secretion.

In all the cases recorded the method employed was the posterior Polya or Reichel operation. I can imagine the anterior method to be a necessity if what remains of the stomach is too far removed from the mesocolic gap to sew the margins of this gap to the stomach wall; but this was possible in all these cases, and in none have there been signs of anastomosis

constriction such as Dr. Charles Mayo has recorded and which led him to prefer the anterior operation.

This operation is well borne. In my view the most important points in the technique are: first, such infiltration anaesthesia as to give satisfactory relaxation; second, sound closure of the duodenum; third, great care in suture of the stomach to the jejunum with small suture gaps; fourth, a watchful haemostasis throughout. In the cases recorded the post-operative recovery was free from complications, from undue shock, from haemorrhage, and from vomiting. The post-operative treatment is as follows: Sterile water is given at once and the patient is encouraged to suck formalin tablets—they allay thirst and keep the mouth clean; on the second day milk, sterilized and alkalized, is added, and on this day an egg, beaten up and divided, is added, and on this day medicine is started for the purpose of controlling the activity of the gastric juice—it contains bismuth carbonate, magnesia ponderosa, and tinctura belladonnae. As the diet is increased powders are given in addition, consisting of calcium carbonate and magnesia.

This operation is the one to be chosen in inveterate penetrating gastric ulcer. Whether it is feasible in a given case cannot be decided until the abdomen is opened. Probably in 10 or 15 per cent. of the cases in which it is desirable it will prove to be not feasible. Some alternative will then have to be adopted. The real alternative is a transgastric operation (excision, or cauterization, or suture, or a combination of these), together with gastro-jejunostomy. If the stomach is so fixed that a posterior gastro-enterostomy is difficult, there is the valuable alternative of pyloroplasty—Finney's operation. This operation, which I should perhaps call gastro-duodenostomy, aims at relieving stasis and modifying the chemistry of the gastric secretion, as does gastro-jejunostomy.

The best contribution to the study of the treatment of gastric ulcer, whether that treatment be surgical or medical, is the collection of careful records. We want to appreciate the immediate risks of operative procedures, the early results, the late results. We want to know much more as to the persistence of the favourable results that are claimed for methods of medical treatment. Impressions and opinions are of little value to the argument; the question requires the same kind of handling as a laboratory problem, and similar methods of recording and analysing results.

THE TREATMENT OF PERFORATED GASTRIC AND DUODENAL ULCER.

BY

A. H. SOUTHAM, M.A., M.Ch.Oxon., F.R.C.S. Eng.,
ASSISTANT SURGICAL OFFICER, MANCHESTER ROYAL INFIRMARY.

THE treatment of perforated gastric and duodenal ulcer is entirely surgical, and the prognosis largely depends on the time when operation is performed. Recovery is contingent on early diagnosis and prompt surgical treatment; for delay almost inevitably leads to a fatal termination. During a period of two years I operated upon a consecutive series of 46 cases of acute perforated gastric and duodenal ulcer at the Manchester Royal Infirmary. Four patients died following the operation, giving an operation mortality of under 9 per cent.

There is still considerable difference of opinion as to whether an ulcer which has perforated will, after operation, give rise to further trouble, and whether gastro-enterostomy is necessary. I have endeavoured to throw some light on this question by following up the after-histories of the cases in this series. The following are the details of the cases:

Sex and Age.

Forty-four of the patients were males and two females. It is remarkable to note the preponderance of the male sex. The youngest patient was 19 years of age, the oldest being a man of 71. The greatest number of perforations occurred between 50 and 60 years of age.

History of Previous Indigestion.

This could be elicited in most cases. In four patients perforation was the first sign, no previous gastric disturbance being present. In a considerable number of the duodenal cases the symptoms of previous indigestion were very slight.

Situation of the Ulcer.

Forty of the ulcers were duodenal or pyloric in situation. In only five cases were the ulcers found to be gastric. There was, in addition, one case of perforated gastro-jejunal ulcer.

Hours Perforated and Operative Results.
The time that had elapsed before operation is shown in the following table, together with the mortality rate:

Hours Perforated.	Duodenal Perforations.			Gastric Perforations.			Total Mortality.
	No. of Cases.	Died.	Mortality.	No. of Cases.	Died.	Mortality.	
1-12 hours	24	0	Nil	2	1	100%	4%
12-18 "	6	0	Nil	—	—	—	Nil
18-24 "	4	0	Nil	3	1	33%	14%
Over 24 "	6	2	33%	1	0	Nil	25%
Total ...	40	2	5%	5	2	40%	9%

This does not include one case of perforated gastro-jejunal ulcer which recovered.

Mortality.

Four patients died following operation, giving an operative mortality of 8.7 per cent. for the series of 46 cases. Thirty-four cases of perforated duodenal ulcer were operated upon within twenty-four hours and all recovered. Six were operated upon after this period and four recovered; the patients who succumbed were both in poor condition when submitted to operation, and died at thirteen and eighteen hours respectively following operation, from shock. Of the five cases of gastric ulcer, two died subsequently from pulmonary complications. One died on the fifth day following operation from acute oedema of the lungs, the second succumbed on the tenth day after operation from bronchopneumonia. Autopsies were held on both these cases. The ulcers were found to be large chronic spreading ulcers near the pyloric end of the stomach. Microscopical examination showed that both the ulcers were malignant, one being a glandular carcinoma, whilst the other was a spheroidal-celled carcinoma.

Death occurred in one of the patients subsequently from acute appendicitis. He had made an uneventful recovery following a perforated duodenal ulcer and had been discharged from hospital. He was readmitted shortly afterwards with a perforated appendix, and died following operation for this condition. All the remaining cases are, to the best of my knowledge, alive at the present time.

OPERATIVE TREATMENT.

Immediately the diagnosis of perforated ulcer has been made laparotomy should be performed without delay. Time should not be spent in attempts to improve the patient's condition; shock can best be relieved by early operation, and a successful result depends essentially on prompt treatment.

The technique of the operation is now so well known that it requires no special description. The perforation is closed with fine thread sutures passed at some distance from the edges of the ulcer. In cases of duodenal perforation the sutures are passed from side to side and thereby avoid narrowing the lumen of the gut. When tightened these infold the ulcer and a piece of omentum is then tained up and stitched over the suture line. I have always found it possible to close the ulcer successfully by suture. Any method other than suture must be attended with a high mortality owing to the danger of leakage.

The peritoneal cavity is carefully swabbed out with gauze swabs, wrung out of very hot saline. Some surgeons advocate irrigation in preference to swabbing, but irrigation adds the diffusion of the extravasated material and increases the risk of subphrenic abscess.

The operation lasts twenty minutes, rarely longer, and subcutaneous saline may be administered whilst it is in progress with advantage. Drainage is seldom employed. In perforation of under eighteen hours duration it is never necessary. After twenty-four hours when there is gross soiling it may be advisable. This is best done through a suprapubic stab incision and the tube removed as soon as possible.

After-Treatment.

The Fowler position is adopted as soon as the patient is returned to bed; rectal salines are given at four-hourly intervals for two days. For the first forty-eight hours the patient is only permitted small sips of water by the mouth; fluids in increasing quantities are given later. An enema is given daily, no purgative being allowed till the seventh day. The stomach is thus kept at rest as far as possible and opportunity given for the healing of the ulcer to start. After discharge from hospital the patient is instructed to take a careful diet for six months. Sodium bicarbonate should be taken regularly for a time, as this appears to diminish the tendency to hyperchlorhydria, and is helpful, both in attending to. This post-operative treatment, so often neglected, undoubtedly assists in obtaining satisfactory results after operation.

Should an Immediate Gastro-enterostomy be Performed?

There is at the present time no general agreement among surgeons as to the advisability and need for performing a gastro-enterostomy simultaneously with the closure of the perforation. Some surgeons advocate that this should be done as a matter of routine in all cases; but it is only by a comparison of the results and experience of different surgeons that the necessity or otherwise of this procedure can be determined.

Perforation of a gastric or duodenal ulcer is an acute crisis, and a successful result depends essentially on early and rapid operation. However quick the surgeon may be no increased risks are allowable, and time should not be spent where it can be avoided. The actual performance of the operation should occupy as short a time as possible, for prolongation must add to the shock and thereby increase the risk to the patient's life.

Lewisohn,¹ who is an advocate of primary gastro-enterostomy, says that the operative recoveries are not impaired by the extra loss of time involved. He, however, admits that a Murphy's button should be used in acute cases "to save undue lengthening of the operation." This contrivance has long since been discarded in England, on account of its dangers and disadvantages. Surely if he has to adopt this means to shorten the operation it were best to leave the gastro-enterostomy until a later date.

Paterson² states that he invariably performs a gastro-enterostomy after closure of the perforation, and thereby greatly improves the patient's immediate chance of recovery. He states that a number of patients die shortly after operation for perforation, either from perforation of a second ulcer, haematemesis, or leakage along the line of suture, and the mortality from these causes is 11 per cent. He considers that these deaths should, to a great extent, be prevented by a primary gastro-enterostomy. I submit these complications should be largely avoidable by making a careful search for a second ulcer and by care in suturing, whilst fatal haemorrhage following simple suture must be a rare event and is not unknown after a gastro-enterostomy. Further, Moynihan³ has shown that even after a gastro-enterostomy a chronic duodenal ulcer may perforate, so that a gastro-enterostomy does not necessarily exclude this risk.

In ulcers situated near the pylorus it is asserted that narrowing will be produced by the suturing, causing subsequent stenosis and recurrence of the symptoms. If the suturing has been carefully carried out this does not often appear to be the case, as I have proved by radiological examination of a number of cases at a later date. Even if some stenosis is produced this does not persist, and we know that attempts to produce occlusion of the pylorus often fail when that object is desired. Again, an immediate gastro-enterostomy is said to simplify the after-treatment and feeding, but I have experienced no difficulty from this cause, and recovery has usually been straightforward and given no anxiety.

It must be allowed that disappointments following gastro-enterostomy are not unknown, even when performed by the best surgeons and with the most approved technique. A gastro-jejunal ulcer is one of those unfortunate complications which occur in a small percentage of cases. Though doubtless a rare occurrence—perhaps 1 to 2 per cent. of all gastro-enterostomies—the possibility must always be taken into account.

In the following case it is reasonable to assume that the man might have recovered with simple suture of the perforation and been able to lead a useful life, but instead his condition is far from satisfactory.

The patient, a male, aged 34 years, whilst on duty in France in May, 1917, was suddenly seized with acute abdominal pain. He was operated upon about three hours later at a casualty clearing station, where he was found to have a perforated duodenal ulcer. This was sutured and a gastro-enterostomy performed. He made a satisfactory recovery, and was placed on home service.

In February, 1919, he was admitted to the Manchester Royal Infirmary with symptoms of a perforated ulcer. The notes of the operation, which was performed by Mr. Alan Roberts, the assistant resident surgical officer, state: "A small perforation (peptic ulcer) found just beyond gastro-enterostomy; fluid in pelvis; ulcer sutured. Scar of old ulcer seen near pylorus; no drain." He died four weeks later.

On June 2nd, 1920, he was again admitted. I operated immediately, and found a second ulcer, and the anastomosis. This was closed in the usual manner. He made an uninterrupted recovery, and went home on June 23rd.

Walton⁴ advocates that a gastro-enterostomy should always be performed simultaneously with the closure of the perforation, except when the patient is very ill. In 51 recorded cases treated by this method he gives a mortality of 35.2 per cent. and states that this figure is admittedly high. Pfeiffer and Deaver⁵ are also advocates of a primary gastro-enterostomy, and in their paper quote statistics to support this view. They assert that the mortality is not increased by this procedure if it is carried out quickly and not attempted in cases obviously shocked. They urge that gastro-enterostomy is the acknowledged treatment for an ulcer in the pre-perforative condition, and so should be combined with suture after perforation. There is, however, a considerable difference between the chronic duodenal ulcer for which a gastro-enterostomy carried out as a routine operation usually gives most satisfactory results, and the type of duodenal ulcer which undergoes acute perforation.

It is, I think, now generally recognized that there is a variety of acute perforating duodenal ulcer which, when treated by inversion and simple suture, may be followed by a permanent recovery and no subsequent symptoms make their appearance; whereas a second type of ulcer, treated on similar lines, may be followed by a persistence of symptoms which can only be relieved by a further operation. One must admit that it is difficult to find a satisfactory explanation of this fact, owing to our lack of real knowledge of the cause of gastric and duodenal ulcer.

An ulcer is probably produced by the action of bacterial toxins, or, as Mayo⁶ has suggested, by a localized thrombosis or infarction emboli of bacteria, causing a lowering of the resistance of the mucous membrane, which then undergoes digestion in the presence of the gastric juice.

Now certain cases of ulcer, particularly the small and soft type of ulcer, will under careful medical treatment heal; and, again, other cases after perforation and simple suture may show no evidence of ulcer when examined at a later date. To explain the mechanism whereby some cases fail to heal under the above conditions it is suggested that there is some accessory factor present which prevents healing and leads to a continuation of symptoms.

What this additional factor may be is at present unknown; it may depend on some abnormal condition of the gastric juice, or perhaps it is dependent on some product of bacterial activity.

It appears probable, then, that there is a type of acute perforating ulcer, more commonly found in the duodenum, which, when put at rest by infolding and suture, combined with careful diet, will result in healing. If an ulcer can heal under these conditions—and that this may happen is shown by the evidence of healed scars—it is surely better to leave the stomach in its natural condition without the added complication of a gastro-enterostomy; whereas if the ulcer should subsequently prove to be of the unhealable type, a gastro-enterostomy can be performed with greater safety at a later date to relieve the symptoms. As is subsequently shown, a gastro-enterostomy does not appear to be necessary in a large proportion of cases.

The Need for Secondary Gastro-enterostomy.

It has already been pointed out that there are a number of cases which appear to heal after suture and give rise to no further symptoms, and it is only by carefully following up the after-histories in these patients that it is possible to tell what the ultimate result will be in each case. With this object in view I have followed up the after-results in the 37 surviving cases of perforated duodenal ulcer in this series treated by simple suture. The period that has elapsed since operation varies up to two and a half years. In four of these cases a secondary gastro-enterostomy became necessary at a later date.

Twenty-eight patients have for periods up to two years remained free from any gastric disturbance. Five patients suffer from symptoms of digestive discomfort; these have been so slight and their general condition is so satisfactory that further treatment has not been considered necessary. Twenty-four of these patients have been readmitted to hospital, at different periods after their operation, for radiological examination of the stomach and duodenum. This has been kindly carried out for me by Dr. J. B. Higgins, radiological registrar to the Royal Infirmary.

The x-ray examination was carried out with special reference to the condition of the stomach itself, whether there was any evidence of delayed emptying, and if any degree of pyloric obstruction or spasm was present.

The report of the radiologist has been identical in twenty-two cases. He states: "The stomach empties satisfactorily; and there is no delay in emptying. The food passes the duodenum normally, and there is no obstruction." Some irregularity of the duodenum was noticed in several of the cases. In two cases he reports: "The stomach was atonic and the duodenum was not satisfactorily filled." The first of these cases has been free from indigestion since his operation. The second keeps well unless he eats a heavy meal; then he feels some ill ease and flatulence.

A study of the after-histories of cases of perforated duodenal ulcer treated by simple suture shows that in the series under review 99 per cent. of cases required no further operative treatment. Apart from the cases already mentioned, no patient had reported himself as having relapsed up to the time of this record. In 10 per cent. of cases a secondary gastro-enterostomy was necessary on account of recurrence of gastric disturbance; the results of this operation have been completely satisfactory.

These four cases all gave a history of indigestion extending over a prolonged period, and at the operation were found to have chronic ulcers. The symptoms of indigestion recurred within a few months after perforation. It would appear from this that cases giving a long history of indigestion are less likely to show a permanent cure after simple suture than cases with a short history and mild symptoms.

Subsequent Treatment in Cases of Perforated Gastric Ulcer.

The after-treatment in these cases requires special consideration. It is undoubtedly a fact that perforated gastric ulcer is a more serious condition than perforation of a duodenal ulcer, both as regard its immediate and remote results.

Of the five cases of gastric perforation which came under my care two were proved to be malignant at necropsy and microscopic examination. A third case appeared malignant at operation and was in poor condition when he left hospital; he was alive two months after operation, but has not been heard of since that time. The fourth case, a female with perforation of a large chronic ulcer in the anterior stomach wall, still suffers from pain after food, but refuses further operation.

The last case has written to me recently from Birmingham, where he was in hospital under treatment. He had a perforation of the anterior stomach wall about one inch in diameter, and had suffered from indigestion for years. He states that he still suffers from flatulence and vomiting, and it would appear as if some further operative treatment will be necessary. It is not within the scope of this paper to discuss the relationship of ulcer and carcinoma of the stomach, but it must be realized that the types of ulcer found in the stomach and duodenum differ widely.

The duodenal ulcer is often a simple, small, punched out ulcer, whilst the gastric ulcer may be a large chronic and spreading area. Further, the fact that a malignant ulcer of the duodenum is almost unknown, whereas the malignant ulcer of the stomach is of comparatively common occurrence, must be remembered. It is suggested, therefore, that it might be safer to regard all large and chronic ulcers of the stomach as potentially malignant, and treat them as such at a later date by some form of excision wherever practicable. This would be more likely to produce a permanent cure than a gastro-enterostomy alone, which operation is often unsatisfactory for this condition.

IN the United States during 1920 lethargic encephalitis was given as a cause of death on 1,505 death certificates, a death rate of 1.7 per 100,000 of the population; in New York State 364 deaths from this cause were reported, a death rate of 3.5 per 100,000 of the population.

A RECENT report issued by the United States Public Health Service announces the demonstration of an anaerobic organism producing a soluble toxin which affects animals in a manner similar to that of the botulinus organism, but is not neutralized by polyvalent botulinus antitoxin. The organism apparently differs markedly from the botulinus isolated in the United States, and is possibly more nearly related to the European type described by von Ermengem in 1912, although it differs from this in certain respects.

HEREDITARY MICROPHTHALMIA.

BY

W. M. ASH, M.B., B.S.LOND., D.P.H.Vict.,
ASSISTANT COUNTY MEDICAL OFFICER, LANCASHIRE.

THE following history of a family affected with congenital blindness. I will refer to statistics in order that the prevalence of congenital blindness may be appreciated. The most recent reference is in an article on "Cause and prevention of blindness," by Mr. Bishop Harman, in the *BRITISH MEDICAL JOURNAL*.¹ Of the total number of cases of blindness between 3 and 4 per cent. are congenital; Magnus, in Germany, found 97 cases in 2,528 cases, or 3.83 per cent.; Trousseau, in France, 304 per cent.; Dumont, in the Paris Blind Asylum, 3.7 per cent.; Oppenheimer, in New York City, 3.84 per cent. In the United States of America, according to the census of 1890, of 50,411 blind, 4,267, or 8.46 per cent., were recorded as congenitally blind.

Heredity and Consanguinity.

In the eleventh U.S.A. census 43,326 blind persons reported 8,342 blind relatives—that is, 19.25 per cent. had such relatives; whilst of 4,156 congenital blind, 1,608, or 38.7 per cent. had blind relatives. From this it appears that the proportion of blind relatives was twice as great amongst the congenital blind as amongst the blind from all causes.

Mr. Bishop Harman, referring to congenital defects, says: "A few are hereditary—that is to say, the same defect is found repeatedly in the same family for two or more generations."

The influence of consanguinity was investigated by Trousseau,² who reached the conclusion that, "independent of heredity, consanguinity does not play any rôle in the production of blindness." Magnus also holds that there is no proof that consanguinity is a cause of blindness.

That heredity is a cause of blindness seems certain, as the cases which I am reporting go to prove. The diseases of the eye which are most frequently transmitted from parent to offspring are:

- Malformation—for example, coloboma of iris and choroid.
- Microphthalmia.
- Persistence of the pupillary membrane.
- Congenital cataract and amblyopia.
- Nystagmus.
- Albinism and retinitis pigmentosa.

These may be transmitted in the same or like form. It is, perhaps, not out of place to mention here that myopia is frequently hereditary. Moles, quoted by Trousseau,³ stated that 67.5 per cent. of cases of myopia are hereditary.

The accompanying genealogical tree of the "H." family,

Recently the other two boys were admitted to the same institution, but the epileptic, on account of this defect, had to be discharged.

Prevention.

From the genealogical table it will be seen that the tendency to transmit blindness by the females shows no sign of diminishing, but rather of increasing. Through how many generations the condition may be handed on it is impossible to conjecture. Marriage and parenthood should be avoided by the members of this family, especially by the females. The male members show no tendency to transmit the disease as far as can be ascertained.

I am indebted to Dr. J. J. Butterworth, County Medical Officer of Health, Lancashire, for permission to publish this case, and to Mr. W. H. Illingworth, of Henshaw's Institution for the Blind, Old Trafford, for allowing me to make use of the report on one of the cases.

THE INTERPRETATION OF SYMPTOMS IN DISEASE OF THE CENTRAL NERVOUS SYSTEM.

ABSTRACT OF THE GOULSTONIAN LECTURES, DELIVERED BEFORE THE ROYAL COLLEGE OF PHYSICIANS,

BY

ANTHONY FEILING, M.D., F.R.C.P.,

PHYSICIAN, HOSPITAL FOR EPILEPSY AND PARALYSIS, LONDON.

LECTURE II.

In his second lecture Dr. Feiling dealt particularly with alterations in muscle tone and changes in reflexes. Alterations in muscle tone were one of the most common and most important symptoms of disease of the central nervous system; therefore the recognition and interpretation of the more characteristic of these changes was very necessary. He did not propose to discuss the exact mechanism by which these changes were produced; he restricted himself to emphasizing the clinical value of an appreciation of the different changes of tone.

Hypertonus or Increased Tone.

With regard to hypertonus, the terms "spasticity" and "rigidity" were applied more or less indiscriminately to states in which the musculature of the limbs exhibited an increased tone. The textbooks stated that it was lesions of the upper motor-neuron which caused such spasticity. This was true, but was far from being the whole truth. The upper motor neuron was a very complex mechanism, by means of which many different systems of fibres acted on the lower motor neuron. It was possible to distinguish broadly between the hypertonus of pyramidal lesions—that is, lesions interrupting the cortico-spinal tract—and that of extrapyramidal lesions, not merely by any differences in the reflexes, but by the intrinsic characters of the hypertonus itself. Thus in hemiplegia due to a vascular lesion of the internal capsule or its neighbourhood, after the preliminary stage of flaccid palsy, if the limbs became spastic, the characters of this spasticity exemplified the particular changes in muscle tone which occurred in lesions of the pyramidal tracts. There was a marked difference between the arm and the leg. The leg was stiff in a position of extension, but in the arm it was the flexors which showed increased tone, the characteristic attitude of the arm being adduction at the shoulder and flexion at the elbow and wrist joints. Cases due to cortical or sub-cortical lesions did not usually show so great an increase of tone. In the arm the hypertonic muscles would yield to firm passive extension at the elbow-joint. They often gave way somewhat suddenly, so that, unless contractures had occurred, the arm could be almost fully extended. If the arm were then flexed again at the elbow, and the patient told to extend it himself, there might be extension to some point, and then the flexor muscles became tonically contracted and so prevented further extension.

But in disease of the extrapyramidal motor system the position was different. Paralysis agitans, for example, began in many cases with a hemiplegic distribution of symptoms, and might remain in this state for a considerable time, the onset of the tremor being delayed perhaps for many months.

Abdominal and plantar reflexes, especially in old people, were not always easy to elicit. The character of the hypertonus was different here from that in hemiplegia due to lesions of the pyramidal tract. Instead of finding hypertonus in the flexors of the arm and extensors of the leg, there was a diffused rigidity affecting all muscles more or less equally, and not altered by voluntary or passive movements of the limb. This was often found in cases of encephalitis lethargica, apart from the cases which exhibited the Parkinsonian syndrome.

Wilson, in his original description of progressive lenticular degeneration in 1912, clearly distinguished between the universal diffused stiffness of muscles in that condition and that found in the ordinary cases of hemiplegia. In spastic paraplegia due to disease of the spinal cord a careful study of the nature and distribution of the rigidity present could give a valuable insight into the degree of damage to the cord. These differences in the character of the hypertonus has been emphasized by the study of cases of gunshot injuries during the war, and notably by the work of Head and others. Lesions of the cord which, on the motor side, interfered with the function of the pyramidal tracts only, would cause paraplegia in extension. More severe lesions produced paraplegia in flexion. In some cases this study might also help in localizing the anatomical site of the lesion, and aid in determining the nature of the pathological process, for the more peripherally placed lesions would involve more the pyramidal tracts, with the production of paraplegia in extension; and the more centrally placed lesions would tend to involve other tracts as well, with the production of paraplegia in flexion. This was of real value in the matter of prognosis.

Decerebrate Rigidity.

Dealing next with decerebrate rigidity, the lecturer said that numerous observers had recently claimed to have found in certain disorders of the central nervous system a clinical picture under this name. Wilson had reported cases in which, with impairment of consciousness, there was tonic rigidity of trunk and limbs, with exacerbations in the form of tonic or postural fits. The typical posture was, with arms rigid, adducted at the shoulder, strongly extended at the elbow, with internal rotation and marked pronation of the wrists. In Wilson's cases the pathological conditions found were very various, including cerebral tumour, cerebral haemorrhage, and tuberculous meningitis. Recent papers, however, did not fully agree with Wilson's views, and it was pointed out that only in the matter of posture did the picture resemble that of decerebrate rigidity, and that there was lacking the other characteristics, particularly those described by Sherrington. As to whether conclusions of clinical value could be drawn from these cases, the lecturer said that this phenomenon represented disturbance of function only; it did not necessarily indicate permanent structural disease. He quoted cases in which, although the posture was almost exactly similar, the pathological cause varied greatly. One was that of a child aged 2½ years, who was admitted on account of optic neuritis, and during the two months of his illness lay unconscious, flat on his back, with the extensor muscles of the neck and trunk stiff, the eyes being in a position of spasmodic convergence. There was the typical meningeal cry. The positions of the limbs were those already described. After death there was found an infiltrating tumour of the brain, of sarcomatous type, occupying the whole mid-brain, and extending into the crura on each side. The picture, indeed, gave no indication of the pathological process at work; it was merely a sign of disordered function: a lesion had upset the normal balance between the many different systems of fibres which acted on the motor neuron, allowing some particular system to exert an abnormal effect.

Ramsey Hunt had recently elaborated a theory of the dual nature of the motor system. This supposed the existence of two systems: (1) kinetic, (2) static—the first associated with movement, the second with the maintenance of posture. Movements and postures were regarded by Hunt as of three varieties—reflex, automatic associating, and isolated synergic. Also he postulated three divisions of the nervous system: segmental, paleo-encephalon, and neo-encephalon, each of these containing the two different motor systems—that is, kinetic and static. There was not yet available sufficient accurate knowledge of the functions of the extrapyramidal system alone to warrant the acceptance of this hypothesis in its entirety.

Hypotonia was present in some cases, such as severe instances of acute anterior poliomyelitis. Lesser degrees of

it were often overlooked, yet it was an important guide both as to regional diagnosis and concerning the patient's disability. Lesions of the spinal nerve roots might be responsible for hypotonia. Opinion now in the main inclined to the belief that hypotonia was one of the leading symptoms in disease of the cerebellum or of its efferent nerve tracts; and Gordon Holmes had shown that it was in acute or recent lesions especially that hypotonia was most characteristically found.

Reflexes and Their Limitations.

In the past the study of reflexes and their limitations had tended to dominate the investigation of nervous disease to the neglect of other symptoms, largely because of the greater ease with which disturbances of this kind could be examined as compared with the time and trouble required to investigate alterations in sensation, motion, and changes of tone. Perfunctory testing of reflexes had been too often considered a sufficient examination of a case, and especially in the presence of gross exaggeration was supposed to be diagnostic of organic as against functional disease. This partial truth had led to much confusion and difficulty. The reflexes were of three kinds: (1) Superficial or cutaneous; (2) deep or tendon; (3) organic or motor. As to the oculo-cardiac reflex—pressing firmly on the eyeballs and noting the amount of the slowing of the pulse which occurred, or its absence—Dr. Feilung had not found it to possess any clinical value. The Achilles jerk was best tested with the patient kneeling, and he regarded it as of equal value to the knee-jerk, especially in cases in which the lower parts of the spinal cord or the chorda equina might be involved. In eliciting the cutaneous reflexes the skin should be warm. Abdominal reflexes were apt to be feeble in people with a pendulous abdomen. With regard to reflexes in general a difference on the two sides was much more important than any quantitative symmetrical alteration.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

HAEMORRHAGIC COLITIS.

The interesting communications on haemorrhagic colitis by Mr. Geary Grant (February 25th) and Mr. Lockhart-Mummery (March 11th) encourage me to report the successful treatment of a severe case under my care in 1909. It is the only case of this nature which I have had to treat, and it gave occasion to the one and only operation for appendicostomy that I have performed; for this reason perhaps I have a very vivid recollection of the circumstances. The successful result I attribute to the rationale of one of the methods of lavage adopted after the operation, which I believe had not been entertained previously as a weapon in combating the infection of the colon.

In December, 1903, I was asked by a fellow practitioner to see a man, aged 25, who had been suffering since the previous September from frequent diarrhoea. Early in November he had to take to bed, and the motions, eight to twelve a day, were accompanied by much blood and mucus. There was no evidence of tubercle; he was "running a temperature," was extremely emaciated and anaemic and feeble; had lost nearly 3 st. in weight from his normal 9 st.; pulse frequent, great thirst, tongue dry and raw, face drawn and anxious. There were several badly decayed teeth, and the breath was foul. He appeared to be in the later stages of exhaustion, and though recovery seemed doubtful I advised that he should be removed to hospital and have appendicostomy performed, with subsequent lavage of the colon, on the lines suggested by the late Mr. Keetley, who, I believe, was one of the first to advocate this operation in colitis. Early in January, 1909, he was taken to the cottage hospital, and there I fixed the appendix to the abdominal wall, opening it up a few days later. His condition at this time was very bad, accentuated doubtless by the operation and anaesthesia. There was constant passage of blood and mucus, extreme exhaustion, and vomiting had commenced. After opening the appendix a variety of injections was tried. I can remember saline, hazelnuce, Condy's fluid, protargol; from a pint to a quart of these was given twice or three times daily, and each in turn for five or six days. China clay emulsion had not then come into vogue.

I can recollect some slight improvement with the Condy's fluid, but at the end of January his condition had become desperate; he was quite apathetic, was turning his face to the wall, and the stools, though less offensive, were frequent, and contained much blood and mucus. It was evident that merely washing out the bowel with large quantities of such mild antiseptics as could be borne was not adequate to stop the infection, and it occurred to me that it might be possible to combat it in another way—namely,

by keeping the bowel charged with a dominant and antagonistic micro-organism such as the lactic acid bacillus, growing in an acid medium, with the hope that it might crowd out or displace the (alkaline) conditions of the colon. Sour milk prepared by inoculation with a liquid culture of *B. bulgaricus*, and incubation for forty-eight or more hours, was employed, and a quart of this was used for irrigation of the bowel through the appendix opening twice or three times daily. Within a few days distinct improvement was noticed: the stools were acid, with less blood, and much less offensive, and the tendency to vomiting ceased. The sour milk irrigations were kept up for about a month, being gradually diminished in frequency and amount; blood gradually disappeared, and the patient's general condition improved in every way. He left hospital in May, 1909, convalescent, weighing 7 st., and resumed his work as a clerk in September, 1909, weighing 9 st. In view of the possibility of recurrence the appendix was kept open until October, 1911, when it was closed by Mr. Bailey, F.R.C.S., in St. Bartholomew's Hospital.

I have recently seen this patient after many years; he is in perfect health, was placed in Class B for war service, is now married and the father of a healthy child. There is a slight bulgo at the site of the appendix opening; otherwise the scar is narrow and firm.

There is nothing, of course, new in the idea of using an innocuous organism or its products to antagonize the pathogenic effects of a harmful one, but the striking results in this case were so obvious that it is perhaps worthy of record, and I should be interested to hear if this method, or one based on similar reasoning, has been employed by others.

Wimbledon.

JOHN A. HAYWARD.

Mr. LOCKHART-MUMMERY's remarks (March 11th, p. 412) on the comparative rarity of this disease, and the value of appendicostomy in it, tempt me to write a brief account of two similar cases, the only ones I have seen in twenty years; in neither was a sigmoidoscopic examination made, so I am unable to say if the condition of the colon was the same as Mr. Geary Grant described, or was one of ulcerative colitis with an open vessel in the base of an ulcer, but I imagine this is not of great moment from the point of view of treatment.

CASE I.

A young woman, aged 23, was sent into hospital as a case of colitis with severe haemorrhage, which had been going on for a fortnight. She passed daily 3 or 4 oz. of blood, which was judged to come from about the sigmoid flexure.

She was treated medically, and was given on alternative days large wash-out saline enemata followed by an enema of a pint of solution of protargol; all this was done in the knee-elbow position. For a time it had no effect in checking the bleeding, and my anxiety was becoming acute because she was getting blanched; but happily she then began to lose less and at the end of six weeks the bleeding ceased.

She was kept in bed for a further six weeks, with no signs of a recurrence, but on her first day out of bed the bleeding started again and was nearly as bad as before.

Treatment on the same lines was again begun, and the result was rather more rapid than before, but after four months in bed the bleeding began again as soon as she walked about. The medicinal treatment and the enemata were on both occasions continued for some time after the bleeding ceased.

She had come into hospital on October 8th, 1913, and we were now in the middle of April, 1914, and she was no better. I did appendicostomy, and in a week or two the bleeding ceased and did not return. The rapidity of cure, and the ease and efficiency with which the large bowel was washed out, formed a marked contrast with the methods and results achieved before the operation. She left hospital in due time, and came to me again four years later for the cure of a hernia which had occurred through the abdominal wall by the side of the appendix. She had no return of colitis.

CASE II.

The second case, a girl aged 11, admitted in 1915, was similar in all particulars, save that after a period of observation I straightway did appendicostomy with most satisfactory results.

While on the subject of appendicostomy I may mention that in two cases of perforated gastric ulcer with great soiling of the peritoneum, instead of draining Douglas's pouch by a tube through an incision above the pubes, I have done appendicostomy, drained through this wound, and immediately opened the appendix; through this I was able to run in saline, aperients, and peptonized food (the latter half a pint or more at a time) as the occasion demanded. It appears to me that it is an immense advantage to be able to do this in a patient who is always suffering from shock, general peritonitis, and almost certainly post-anaesthetic vomiting, and, moreover, has a recently stitched up hole in his stomach.

Sherborne, Dorset.

T. MACCARTHY M.R.C.S., L.R.C.P.

British Medical Association.

CLINICAL AND SCIENTIFIC PROCEEDINGS.

MALAYA BRANCH.

At the annual meeting of the Malaya Branch of the British Medical Association, held at Singapore on January 27th, of which an account has been given in the SUPPLEMENT (April 1st, 1922, p. 54), a number of important papers were read, followed by discussions.

Dr. W. FLETCHER read a paper (prepared in conjunction with Dr. A. T. STANTON) on melioidosis, a new disease of the tropics resembling glanders. An abstract of this paper was published in the EPITOME of February 11th, 1922 (p. 24, par. 148). A discussion followed the reading of the paper, and in his reply Dr. Fletcher said that the disease had been diagnosed during life in four cases only. Specimens of blood, urine, and faeces should be sent for laboratory examination in suspected cases.

Dr. J. R. KAY-MOUAT, acting principal of the Singapore Medical School, read a paper upon the functions of a medical school, with reference to local conditions.

He said that the chief duties of a medical school were the dissemination of medical knowledge by the education of students, post-graduate instruction, and literary facilities; the advancement of medical sciences by research, discussion, and publications; and the maintenance of professional unity by *esprit de corps*, social intercourse, and selection of personnel. In Singapore the College of Medicine had been established with a full-time staff, thus eliminating the evils of irregular teaching and inadequate control. Admission of the students had been controlled by raising the standard of the entrance and scholarship examinations, and granting Government-indentured scholarships only to the few best candidates. The plans had been approved for the new medical school, which showed medium-sized classrooms, a large lecture hall and museum, an extensive library, and ample post-graduate and research facilities. Now, when the General Medical Council had recommended the Singapore qualification as qualifying for practice in England, the College aimed at maintaining a standard equal to the British average standard, and recent successes by their students in the higher examinations in London showed that there was no need for anxiety.

The Hon. Dr. D. J. GALLOWAY said that he had been connected with the medical school since its inception, and he now noticed a very great improvement in the standard of the students. He believed that a circumstance of the greatest value to the future school was its proposed inclusion as the medical faculty of the Raffles University of Singapore.

Mr. K. BLACK, F.R.C.S., read a paper upon a defect in the sterilization technique, and later showed some interesting and obscure cases of eye disease among the inmates of the native hospitals.

After Dr. Kay-Mouat had entertained the members to lunch at the Hotel St. George the meeting was resumed, and Dr. MALCOLM WATSON read an interesting paper upon "Quinine and the quinine controversy."

He said that when it was considered that quinine had been known to European medicine for nearly 400 years, and that at the present time hundreds of medical practitioners used it daily in the treatment of malaria, it was remarkable that there was no unanimity in fixing the optimum dose or method of administration. Dr. Watson gave a summary of the history of modern experiments in quinine administration, and said that for some seventeen years he had watched labour forces under the influence of various doses. There were four factors in the experiments—namely, quinine, man, the mosquito, and the malaria parasite. Malaria was not always the same in severity or intensity, while the mosquito was a factor of almost bewildering variety. Man was also a variable factor, some races, such as the Malaysians, being more susceptible to malaria than others, and he rather thought that in a mixed labour force of Tamils and Malaysians, the Tamils, even without quinine, would maintain better health than Malaysians with it. In regard to quinine prophylaxis, he considered that in an intensely malarial place it should certainly be taken, not with the idea that it would prevent infection, but that it redressed its severity. In a less malarial place, where one might expect to live for many months without being likely to contract the disease, it was less important for healthy people to take it; in such places it was, however, important to give quinine continuously for at least three months to those who did contract the disease, which would certainly reduce the danger to others. In regard to the dose, at least 10 grains daily should be taken, preferably in solution and with meals—he laid particular stress on the last point.

In the discussion which followed Dr. KAY-MOUAT commented upon the possibility of the dangerous effects of taking quinine sulphate which had been kept for a considerable period; many other members gave their experience of quinine prophylaxis.

Dr. H. J. GIBBS read a paper upon the subject of ethics, tracing its influence in medical practice from Greek mythology.

Reports of Societies.

THE ROUTE OF RENAL INFECTION.

Mr. KENNETH WALKER, at a meeting of the Section of Urology of the Royal Society of Medicine on March 30th, introduced the subject of renal infections, and gave an account of his experimental work on the method of spread. The history of this subject, he said, illustrated the tendency for the pendulum to swing from one extreme to the other in any controversial matter. Ten or twenty years ago a good many infections which were now regarded as blood infections were looked upon as infections spreading from the bladder to the kidney. With the improvement of diagnostic methods it was found that the majority of these infections were not true ascending infections, and observation of animal experiments proved that infection did not spread so readily from the bladder to the kidney as was supposed. Two conditions were necessary for such spread—namely, obstruction of the flow of urine, and incompetence of the valve guarding the entrance to the bladder—and these were not conditions found in ordinary cases of renal infection. Thereupon the pendulum swung right back so that for a time it seemed to be denied that infection ever spread from bladder to kidney except as a complication in very grave urinary trouble such as complete retention. He believed that this was to disregard certain possible routes of infection, especially the lymphatics which ran around the ureter and into its insular coat, though he would not say that this was as common a route of infection as the blood stream; it was impossible to tell how common it was. The first experimental work done on this subject was by an Italian, Paladino Blandini, who inoculated the urethrae of guinea-pigs with some definite organism and after an interval of twelve hours made a careful bacteriological examination of various portions of the genito-urinary tract. He found that after twelve hours he could recover the organism at the upper end of the ureter and at the kidney. The lecturer had repeated this experiment, inoculating the anterior urethrae of guinea-pigs with *B. prodigiosus*, and killing the animals after from thirteen to eighteen hours. The heart's blood on each occasion was found to be sterile, and yet in each animal one got a luxuriant growth from the upper end of the ureter. The kidney, stripped of capsule, was sterile, and, in spite of this infection of the upper end of the ureter, the urine also was sterile. He had used, instead of organisms, carmine particles, and had recovered these from the upper end of the ureter. He tried also Gram-positive organisms which he could stain, and, although in this case there were no organisms in the ureter, outside the ureter, presumably in the lymphatics, there were masses of such organisms. He instanced the corroborative experiments by Teale and Embleton in a communication to the Section of Pathology of the Royal Society of Medicine in 1914; these workers described a bacterial spread by the lymphatics.

More recently (Mr. Walker continued) he had had the opportunity of following up the investigation in the *post-mortem* room on the case of an old man who had been admitted to hospital with complete retention; and again in a clinical case, a woman admitted for dysmenorrhoea, who developed kidney trouble subsequently, and on whom he operated. Here he found periureteric infection and infection of the perirenal tissue, which appeared to have ascended. Both the *post-mortem* and the clinical case confirmed the results of his animal experiments, that organisms did reach the upper end of the ureter, and perhaps also the kidney, presumably by way of the lymphatics. It might seem as though the organisms, to reach the kidney, would have to travel against the direction of the lymph stream, but it had to be remembered that the lymph stream was sluggish and indefinite, with cross-ways and channels. He pictured the various connexions of the lymphatics, and pointed out (bearing on his clinical case) how in the female the lymphatics of the ureter were connected with those of the genitalia. What was true of pyogenic organisms he thought might also be true to some extent of the tubercle bacillus. Perhaps it was rash of him as a surgeon to enter the province of the physician, but it was an interesting speculation whether the radioactivity with which organisms reached the kidney by way of the lymphatics might not explain the etiology of certain types of chronic interstitial nephritis. Although the etiology was still in dispute, he believed that this was more and more regarded as an inflammatory and infective lesion. It was generally

assumed that the infection reached the kidney by way of the blood stream, but one had to consider the possibility that it was by way of the lymphatics. The lesion which would be caused by repeated lymphatic infection by an organism of low virulence would be fibrosis of the cortical area with thickening of the capsule. The fact that no evidence of this chronic irritation of the kidney would be furnished clinically by examination of the urine for organisms rather lent support to the theory that repeated invasions of the superficial lymphatic plexus might be the cause.

His conclusions were (1) that although the blood stream was the commonest route by which an infection reached the kidney, organisms might also reach it by the lymphatics around and in the noster; (2) that the kidney capsule was an important link in this lymphatic chain, and was the situation in which organisms were most consistently found in cases of ascending infection; (3) that in early cases of lymphatic infection of the kidney no organisms were found in the urine; (4) that there were reasons for believing that the tuberculous infection of the kidney might take place along a precisely similar route; and (5) that the lymphatic route might explain some cases of chronic nephritis, and it was possible that decapsulation might not be without effect on the development and progress of such a condition.

Sir THOMAS HORRER, who presided, said that many of those present were aware that Mr. Kenneth Walker had been interested in this aspect of urinary tract infection for a number of years, and it was a good thing to have a somewhat epitomized version of his work before them. He would not care to undertake a criticism of the experimental work involved, nor to estimate the extent to which Mr. Walker's conclusions were justified. But one obvious criticism might be stated in the form of a question: Was the distribution of an organism as found on section necessarily indicative of the route by which the infection had taken place? Granted that it was highly suggestive, was it conclusive? He instanced the condition sometimes encountered in undoubted haematogenous infection, such as by *Staphylococcus aureus*. One of the first clinical expressions of the pyaemic state so caused might be a perinephritic inflammation, proceeding rapidly or slowly to suppuration. It was taken for granted, in such a case at all events, that the route of infection was the blood stream; but if the same kind of observation and deduction were applied in this case as Mr. Walker had applied in the case which he considered afforded clinical corroboration of his lymphatic stream theory the same conclusion might be reached. Even in the post-mortem room the actually infected portion of the kidney demonstrable in the case of pyaemia the result of *Staphylococcus aureus* infection was very small, whereas the involvement of the kidney capsule and the perirenal tissue was very great. But the same thing applied to other structures and other lymphatic systems than those of the kidney. It was the same in the lung. The first clinical evidence of the thoracic pyaemic state in *aureus* septicaemia might be not the existence of a true pulmonary lesion but the existence of pleurisy, and yet it was well known that the pleurisy was really secondary to the lung involvement. He might quote subphrenic abscess as another instance. He was very doubtful whether the clinical case which Mr. Walker had brought forward did much, if anything, to confirm his conclusions. The inference was that the supposed trauma of the cervix in this young woman was the cause of the perimaterial infection; but there were other possibilities. The kidney might have "flared" as a result of a haematogenous infection, even though the blood stream was found to be sterile. But the whole subject was so important, and so little was known at present about routes of infection, that one could only welcome the very solid and important addition to the general knowledge which Mr. Walker by his experiments extending over many years had contributed. It was a subject the study of which should be extended both by experimental work and by the correlation of clinical observation therewith.

Mr. FRANK KIDD said that he had the highest admiration for Mr. Kenneth Walker's work, but clinically he did not feel justified in going so far as Mr. Walker had gone in his deductions from his animal experiments. He referred to the rarity of bilateral tuberculosis of the kidney as rather against his suggestion of the tuberculous infection going down the ureter on one side and apparently going up on the other. Dr. DENNIS EMBLETON referred to some work which he and Dr. TEALE had done since the publication of their former paper, which bore out what Mr. Walker had said regarding the ascending infection, but he pointed out that the process of spread was very slow, which might explain the point raised

in objection by Mr. Kidd. Dr. F. H. TEALE said that in the animal experiments the difference between lymphatic infection and haematogenous infection was quite definite. Mr. C. A. R. NICH described four cases which showed that the spread of organisms was probably periureteral both up and down the lymphatics. Mr. KENNETH WALKER, in replying, said that he had tried to carry out his observations in as many fields as possible, so that he should not be tempted to lay too much stress upon any one of them. He referred at greater length to his clinical case, and gave his reasons for considering the infection to be by the lymphatic rather than by the blood route.

PHYSIOLOGICAL PRINCIPLES UNDERLYING HELIOOTHERAPY.

A MEETING of the Manchester Clinical Society was held in the Physiological Theatre of the Manchester University, at which ninety-eight members were present, with Professor G. R. MURRAY, the President, in the chair, when Professor LEONARD HILL delivered an address on the physiological principles underlying light treatment and heliotherapy.

Dr. HILL pointed out the great differences in the expectation of life between rural and urban populations; for instance, 61 years at birth for females in Westmorland against 46 at Middlesbrough; similarly at age 20 Surrey County had an advantage of nine years over Oldham. Turning to occupations, and taking the clergy as the standard of low mortality, agriculturists came next, in spite of low wages and bad housing, while factory workers gave much higher figures. Environment had to do with these differences. In regard to tuberculosis, unsalted races who came in contact with the disease suffered a very much higher mortality; so did very young children. Almost all were infected in our cities, and while small doses might vaccinate and protect, large repeated infections destroyed life; young children ought to be protected from such by removal from infected parent or teacher. In the future a successful vaccine treatment might be established, or the discovery of a drug which like salvarsan would have a specific curative effect. Supposing, however, tuberculosis were prevented and bad environmental conditions continued, other diseases would take its place and keep up a high mortality; such was the evidence of historical medicine.

Environment acted through bad atmospheric conditions, neglect of rest and exercise in the open air, over-fatigue, and ill-balanced diet. As to the first there was no increase of CO₂, or deficiency of oxygen, or organic chemical poison that mattered in the air of crowded rooms. Massive infection occurred in such from carriers of catarrhal disease, and open windows or efficient fan ventilation lessened that. Dust from clothes soiled by excreta, as well as saliva spray coughed and sneezed out, spread infection. Road and trade dusts, clogging the respiratory membrane, might lessen the protective action of the secretion, lately demonstrated so strikingly by Flemming. One kind of dust was particularly noxious—namely, free silica dust breathed by miners in quartz, and by gritstone, sandstone, and granite workers. Free silica breathed continually in high proportions produced fibrosis of the lung, which in the presence of infection was followed by tuberculosis. Injected colloidal silica lessened resistance of animals to tuberculosis, and caused in them fibrosis of kidney, liver, etc. (Gye and Kettle). Organic dusts and coal dust appeared to be harmless. Coal-miners were a healthy lot; they worked often stripped to the waist, in well-ventilated places, were not crowded together, had good food and enough leisure.

Smoke pollution of the air was the result of most inefficient methods of using coal. From 75 to 95 per cent. of the thermal energy of coal was wasted; out of every three tons used in this country, if one were properly used there might be two left over for export—that is, without raising any more coal than now. Coal should be distilled, the gas used for heating, etc., the coke for raising steam and electrical power and light, and the valuable by-products saved, such as tar and ammonium sulphate. The economic loss due to smoke fog was gigantic—waste of time due to obsolete transport, waste of artificial light, of human energy in cleaning and re-decorating and washing clothes, waste in destruction of buildings and vegetation. The last helped to make a deficiency of vitamins, for little or no green food could be grown in smoky courts or gardens. The poor lived on white bread, margarine, sugar, and tea—separated, artificial products deficient in salts and vitamins. Such a diet, and confine

ment in close tenements led to rickets, tuberculosis, etc. Experiment proved the dependence of rickets on those two factors. The smoke fog robbed us of sunlight and its cheering, health-giving influence, and drove people away from open-air to indoor amusements. Overclothed, in close, warm rooms, we were surrounded with a humid, tropical atmosphere, entirely different from the stimulating effect of open air, with its high evaporative power, exerted on the skin and respiratory membrane.

Air saturated at 0° C. held about 5 grams of water vapour per cubic metre, while that leaving the lungs saturated at 33.5° C. held nearly 40 grams. It was calculable that a man sleeping out of doors and taking vigorous exercise might evaporate three times more water from his lungs than a sedentary person living indoors. To make good the evaporation much more arterial blood and lymph flowed through the respiratory membrane, and kept up its immunity to infection.

The katablometer, dry and wet bulb, enabled one to measure the cooling and evaporative powers on a surface, at body temperature, and to estimate the vast difference between open-air and indoor life. This instrument showed that people were commonly living and working in atmospheres with as low cooling and evaporative powers as were found out of doors in the shade in humid, tropical climates, which were admittedly enervating to white men. Many readings had been taken in the workshops of printers, boot and shoemakers, cotton weavers and spinners, and potters, and showed that readings were very frequently below the very moderate standards set up by the lecturer. It was significant that the general mortality increased with the lowness of the readings in these four trades. People, by shutting themselves up, over-clothing their bodies in their absurd fear of catching cold, lived in a humid, tropical atmosphere, and reduced their metabolism (body heat production); this reduction entailed loss of muscle tone, flabby bodily habit, depression of breathing and circulation, ill digestion and absorption of food, loss of appetite, constipation, dyspepsia, etc.

Children at Loysin under Rollier, and at the Treloar Hospital under Garvain, were exposed, often more or less nude, to the far higher cooling and evaporative powers of open air, and to sunshine. They responded with a 50 to 100 per cent. increase of metabolism, hard muscles, improved health, and arrest of their tuberculous disease. In place of temperatures of 32° C. dry and 30.5° C. wet bulb under the clothes, between the skin and shirt, which obtained in a room, the temperatures might be 14° and 11° when bicycling on a winter day downhill. The cheek temperature in badly ventilated factories was about 34° C., while it was 30° in well-ventilated rooms, and anything down to 20° C. in cold winds out of doors. There was a close relation between cheek temperature and body heat production. How open air affected metabolism was shown by the fact that the resting metabolism of city dwelling adults—about 1,600 to 1,700 calories per diem—was raised about 35 per cent. at the east coast, and when on a holiday. Puddling about it was at the rate of about 8,000 calories per diem, swimming 12,000 to 15,000 calories, paddling along the shore, one mile in fifteen minutes, 15,000 to 16,000 calories. The stimulation of metabolism and bracing up of the muscles by cold and exercise was a large part of the good effect of such a holiday. The abundance of light from sun, sky, and sea also acted beneficially.

Children did better at the Treloar Hospital during summer than winter owing to the sunshine. This was not due to ultra-violet rays, for these did not penetrate more than about 0.2 mm., but the luminous rays penetrated and were absorbed by the blood in the skin, and there changed into heat rays, probably also effecting chemical changes of a nature as yet unknown. In preventing rickets exposure to sunshine made good a diet otherwise deficient—for example, so much exposure to sun was equivalent to so much phosphate in the food. Pigmentation resulted as a sign of such changes in the skin, and, once set up, protected from sunburn. Patients had to be exposed to the sun gradually so as not to be damaged by sunburn, and a high cooling power was required to prevent overheating of the body and stimulate metabolism during the sun exposure. Given such cooling power, exposure of the body to the sun was of advantage to phthisis as well as surgical tuberculosis. Resort to the Alpine winter climate (such as that of Montaux, studied by the lecturer), with its cold, dry air and warm sunshine, enabled such treatment to be continued during the worst months of the English winter.

A number of lantern slides were shown of this treatment carried out at the Treloar Hospital by Garvain, and at

Loysin by Rollier. The successful treatment of the wounded and febrile and of neurotic and insane patients by open air was also commented on, and the extension of such treatment generally urged.

TREATMENT OF FINGER INJURIES.

At a meeting of the Manchester Medical Society, held on March 22nd, with Sir WILLIAM MILLIGAN, the President, in the chair, Mr. R. R. KERR read a communication on "The operative treatment of injuries to the fingers." He urged the importance of simple prophylaxis of sepsis in workshops. Where, however, the lesion had become septic and involved the pulp and the end of the phalanx, the incision should never be made in the centre of the pulp down to the bone, but at one or even both sides, just behind the nail. By this means the pulp might be evacuated, involved bone dealt with, and the very valuable pulp saved. To splint a badly injured finger was hardly ever justifiable. If splints were used and the digit became stiff, it was in the extended position, and the owner of it was in a parlous condition. It was far better to let the injured finger heal and become stiff (if that could not be helped) in a position of rest, the semi-flexed position, which was that of greatest usefulness. A further point was that if a finger were so damaged that its function could not be restored, it should be amputated at once. With regard to amputation the principle of saving as much as possible was very dangerous. The guiding finger and by far the most important was the index. When the terminal phalanx of this digit was lost, but the stump well covered and the other joints mobile, it could still do most of its work; but if the remnant were stiff and only including the proximal phalanx or the metacarpal bone it could not do the work of the index, and no other finger could because of the jutting-out and awkward stump. If, however, the index were now amputated right to the base of the metacarpal bone and the tendons also cut well back, the thumb and the middle finger rapidly closed in, and the middle finger could easily be taught to do the work of the lost index. The same point held with regard to the other fingers. After removal of the metacarpal the other fingers closed in and full function was restored for practical purposes.

Operation for Osteo-arthritis of Hip.

Mr. H. PLATT followed with a communication on the operative treatment of osteo-arthritis of the hip-joint. He discussed the various operative measures applicable in the treatment of monarticular osteo-arthritis of the hip-joint. He pointed out that although this affection was most frequently encountered in middle-aged individuals, it was by no means limited to this age period. In his experience three broad clinical types could be distinguished: (1) infective, (2) traumatic, and (3) secondary, where the active arthritic process was superimposed on a hip-joint which in early life had been the seat of a deformed process such as pseudo-coxalgia or arthritis deformans juvenilis. In the symptomatology of osteo-arthritis of the hip, the early stage with its characteristic severe sciatic pain, and the later stages with the progressively increasing fixation of the joint, were briefly described. Although correct mechanical treatment in the early stages would be likely to render unnecessary any major operative procedure later, yet in the practical handling, of this condition the surgeon was too often confronted with the fully matured arthritis and its consequent serious disablement. Four classes of operative procedure were considered: (1) Manipulation under anaesthesia—suitable for picked cases with arthritic changes of a moderate degree. (2) Removal of osteophytic deposits—the operations in this class had a limited application, inasmuch as such bony deposits were rarely the prime cause of the pain or limitation of mobility. (3) Arthrodesis—surgical fixation of the painful hip-joint was ideal in theory but difficult to achieve, and constituted an operation accompanied by a good deal of shock. For this reason, and owing to the necessity of prolonged fixation and protection from weight-bearing, the operation was suitable only for younger individuals. (4) Excision of the head of the femur. The value of this operation was emphasized, and in particular its suitability for older patients; the operation as performed by the reader of the paper was reconstructive in type. A detailed account of the technical steps involved in its performance was given.

Mr. G. JEFFERSON read a paper on the operative treatment of depressed fractures in infants and children. He urged that the old practice of leaving this condition to nature was

wrong. It was often impossible to tell in a child what was the condition of the brain under the fracture. Operation should always be carried out, and consisted in either elevating the depressed area through a small opening, or where this was not possible in excising the portion of skull affected and placing it back in the reversed position.

Mr. ARNOLD JONES made a communication on nasal obstruction in infants during the first year of life. He pointed out that the common causes of this condition were: (a) Congenital occlusion of the nostrils; (b) the temporary presence of mucus secretion in the nose and engorgement of the nasal mucosa during the first few days of life; (c) congenital syphilis; (d) mongolism; and (e) adenoids—the commonest. The symptoms usually seen were: (a) inability to suckle efficiently; (b) snoring and suffocation attacks; (c) persistent cough; (d) nasal discharge; and (e) convulsions.

The diagnosis of nasal obstruction was made from the presence of these symptoms. As to the differential diagnosis, congenital occlusion of the nostrils was very rare. A probe would reveal the situation and completeness of the obstructing web. The temporary engorgement of the nasal mucosa was at once relieved by a weak adrenaline spray. Congenital syphilis usually presented constitutional symptoms, the Wassermann reaction being positive. A mongol was recognized by its typical appearance, and adenoids were diagnosed by excluding the other causes. The treatment varies with the cause. In the case of adenoids—by far the commonest cause—surgical removal was simple, efficient, free from risk, and gave excellent results. Of 53 cases operated on from February, 1919, to the end of 1921, 23 had been recently investigated, and the results found to be excellent. No anaesthetic was used. The youngest infant operated on was under one month old.

DERMATITIS EXFOLIATIVA.

A MEETING of the Liverpool Medical Institution was held on March 23rd, with the President, Dr. J. HILL ABRAHAM, in the chair, when Dr. FRANK H. BARENDT related details of a case of dermatitis exfoliativa in a patient (a man, aged 30) who suffered from psoriasis since he was eight years old, and acquired syphilis three and a half years ago. He was free from any outward manifestation of syphilis, his Wassermann test was "slightly positive," but he had psoriatic efflorescences in the scalp and in the right flank. He was treated intravenously with a single dose of 0.9 gram neo-kharsivan, and locally unguentum chrysarobini was energetically applied. One week later the whole of the integument reddened and the epidermis fissuring in all directions was completely shed. At the end of three weeks the clinical picture of pityriasis rubra was displayed. Under oily lotions the skin gradually resumed its natural colour, and at the end of a month desquamation ended. There was no gastro-intestinal disturbance, the urine was free from albumin and sugar, and although he suffered great discomfort and slight fever during its evolution he was never seriously ill. The question of the immediate cause of the skin affection was viewed from several points, and Dr. Barendt could not definitely ascribe its appearance solely to the arsenical preparation. He inclined to the view that it was a case of inveterate psoriasis passing into pityriasis rubra. The patient was now well and free from any skin affection, in which condition he never remembered to have been since early childhood.

Fibrillation and Flutter.

Dr. HAMUS read a short paper on the circus movement in fibrillation and flutter. He pointed out at the outset that the exact method used in physical science was often unsuitable for research in pathological biology since the latter was too complicated and too many sided to find a true expression in a simple formula. He regretted that the problem had been approached from the electrical and not the clinical and pathological point of view. According to the theory the factors which gave rise to flutter and fibrillation disappeared as soon as the abnormal rhythm was established. Flutter and fibrillation might last for years. Just because many years ago a certain part of the auricle showed for a moment a somewhat longer refractory period than other parts, the circus movement came into existence. Once it came into being it continued *ad infinitum*, although the auricle was perfectly normal in every respect. The lecturer pointed out that it was not difficult to terminate such a circus movement; an extra-systole in the "mother" circus would do it. Ectopic auricular impulses ought to be common: disturbance in the conductivity, which is also frequent, ought also to have the same effect,

and yet we did not hear of spontaneous cures of these conditions. Dr. Harris pointed out that whilst in the experiments it was artificial stimuli which brought about flutter and fibrillation, Sir Thomas Lewis and his co-workers did not give any information at all as to the factors which took the place of the artificial stimuli in clinical flutter and fibrillation. This, the most vital point in any theory, which had for its object the explanation of the mechanism of flutter and fibrillation, was left out of account. Dr. Harris maintained that clinical evidence pointed to the fact that fibrillation was due to a functionally or anatomically damaged auricle, and the causes which gave rise to the abnormal rhythm remained after the latter was fully established. Fibrillation in itself was of relatively little importance; what was important was the cause which gave rise to the abnormal rhythm—the damaged heart muscle. In regard to the general principle of treatment, he drew attention to the curious fact that fibrillation and angina hardly ever appear: both were frequent occurrences in the there were actually instances of symptoms of angina appearing as soon as the auricle started fibrillating. The explanation was as follows: The individual beat in the senile heart was forceful, and therefore strained the heart muscle; in fibrillation the majority of the beats were feeble, and there was no such strain on the heart muscle. By abolishing the abnormal rhythm in the senile heart we might expose the patient to danger of angina. Comparison in mitral stenosis cases, with and without complication of fibrillation, did not reveal that the prognosis was strikingly influenced for the worse in cases of the former.

Quinidine in Auricular Fibrillation.

Dr. JOHN HAY read a paper on cardiac failure, with special reference to quinidine sulphate in auricular fibrillation. He emphasized the importance of recognizing in each case the underlying cause for the cardiac failure—toxaemia, hypertension, myocardial fibrosis, the onset of fibrillation of the auricle. He questioned the value of many of the so-called cardiac tonics, and pointed out that a too implicit belief in the power of these tonics to counteract cardiac failure was a distinct danger, and sometimes led to the neglect of other and valuable methods of treatment in the management of the case. He reported his experience of the use of quinidine sulphate in 15 cases, in 14 of which the patients were suffering from fibrillation of the auricle, and in one from paroxysmal tachycardia. In 12 of the fibrillating cases fibrillation was established, and of some standing; in one it was paroxysmal, and in another it developed during the course of acute pneumonia. In 6 of the 14 fibrillating cases quinidine failed either owing to intolerance of the drug or to the development of rapid heart action due to ectopic beats in the ventricle or simply a failure to respond. Of the 7 in whom fibrillation was arrested, in 3 there had been temporary relapses, in 4 the improvement had been pronounced and the cardiac reserve considerably increased. In 3 auricular flutter developed, in one of which it gave way to normal rhythm. In the 15 cases receiving quinidine there was one death. This occurred in the patient suffering from tachycardia. Death occurred suddenly and without warning twenty-four hours after the cessation of the tachycardia and after only 0.2 gram of quinidine had been taken. No autopsy was permitted. The method of administration was described and emphasis laid upon the importance of frequent repetition of the dose. The quinidine administered ranged from 2 to 3 grams daily. In the earlier cases smaller doses were given and the results were not so satisfactory. The dangers of the transition phases were discussed and indications and contraindications for treatment were considered. Quinidine sulphate appeared to be a valuable drug with limited application. Its administration necessitated careful supervision and a clear recognition of the dangers entailed. Dr. Hay said that he was indebted to Dr. Broomhead for help in collecting valuable material.

BACTERIOLOGY OF PNEUMONIA.

At a meeting of the Pathological Section of the Liverpool Medical Institution held on March 9th, with Dr. HILL ABRAHAM, President, in the chair, Professor ERNEST GLYNN and Miss L. DIBBY, assisted by Dr. WALLACE JONES, summarized certain of their investigations for the Medical Research Council on 140 cases of acute lobar and bronchopneumonia.

One hundred and twenty-seven cases were classified as pneumococcal and 13 as non-pneumococcal, for in the latter pneumococci were absent in the sputum, examined both by

cultures and by mouse inoculation. Using the Rockefeller technique for typing the pneumococci cross agglutination was exceedingly rare; some of the "pneumococci," however, were only partially bile soluble and of diminished virulence to mice. The percentage of Types I, II, III, and Group IV, in 96 adult lobar pneumonias was 45.8, 24, 2.1, 28.1—the Americans find about 12 per cent. of Type III. The mortality was 34.1, 36.3, 50, and 11.1 per cent.—the Rockefeller mortality for Type I is about 10 per cent., partly due to the use of serum. In 21 adult bronchopneumonias 76 per cent. were Group IV and none Type III. In children collected statistics showed that the percentage of pneumococcus types in lobar pneumonia was similar to that in adults, but the mortality was lower; while in bronchopneumonia 60 per cent. were Group IV, and the mortality 41 per cent. In 7.8 per cent. of the 127 cases two types of pneumococci were found, usually I and IV; the mortality of these was 40 per cent., compared with 27.5 per cent. for all pneumonias. Pneumococci were cultured from the blood in 22.6 per cent. of 31 cases examined, the mortality of these was 71.4 per cent., compared with 8.3 for the "negatives." Lung punctures were very useful, especially in children, and produced no ill effects; in adults pneumococci were cultured from the lung juice in 45.9 per cent. of 37 pneumococcal pneumonias examined; the mortality of these was 47.1 per cent., compared with 10 per cent. for the "negatives." Though streptococci were cultured from the sputum of the adults very frequently and "influenza" bacilli sometimes, the former were only cultured from the corresponding lung juice once and the latter never. In children 65.6 per cent. of the lung-juice cultures were positive; meningococcus Type II was found once, *B. influenzae* twice, and streptococci once. Of the 13 non-pneumococcal pneumonias, 11 were classed as mainly streptococcal, though mixed infections were common. The percentage "case incidence" in sputum cultures of bacteria in pneumococcal pneumonia and normal saliva respectively were: pneumococcus, 86 and 40, the latter all Group IV; streptococcus, 79 and 100; staphylococci, etc., 54 and 28; Gram-negative cocci, 40 and 80; lactose "fermenters," 25 and 6; non-lactose "fermenters," 15 and 1. As the patients recovered the bacteria in their sputa increasingly resembled those in normal saliva. The bacteria in the sputa of the "deaths" from pneumococcal pneumonia were compared with those of the "recoveries"; in the former there was a higher percentage of pneumococci, *St. aureus*, *St. catarrhalis*, and of lactose and non-lactose fermenting bacilli, but a smaller percentage of streptococci and of most Gram-negative and Gram-positive "staphylococci." It was doubtful whether a true *B. pneumoniae* Friedländer was isolated from the pneumonias; the literature regarding the identity of this organism is confusing, and named strains were found to differ culturally and serologically. *B. influenzae* was found in 18 per cent. of 51 pneumococcal pneumonias; the mortality of these "positives" was 27 per cent., compared with 19 per cent. for the "negatives." The relative incidence of *B. influenzae*, during seven months, in the respiratory tract roughly corresponded with the death rate from influenza in Liverpool. Of 44 empyemas in young children—62.1 per cent. were pneumococcal (Group IV comprised 56 per cent. and Type I 40 per cent.), 31.9 per cent. were streptococcal, or streptococcal and staphylococcal.

Contrary to the usual statements, the mortality of pneumococcal infections was the higher—namely, 45 per cent. compared with 21 per cent. for the non-pneumococcal infections. This difference, however, was partly explained by the lower age of the children with pneumococcal infection. Group IV pneumococcus was much the commonest type found in pneumococcal infections of the respiratory tract other than pneumonia and empyema, also in non-respiratory infections. Definite clinical differences were discovered between Type I and Group IV pneumococcal infections in adult lobar pneumonias and of empyemas of children. Six cases of Type I pneumonia were treated with intravenous injections of Type I serum, 2 apparently with great benefit. The results of the bacteriological investigation of acute lobar pneumonia suggest that though streptococci, *B. influenzae*, and other pathogenic organisms are often present in the sputum, they rarely infect the lung alveoli, but are confined to the bronchioles or perhaps only to the bronchi. This was satisfactory from the point of view of treatment with Type I antipneumococcal serum, especially as one-third of the lobar pneumonia cases in Great Britain are due to Type I pneumococcus.

ACUTE TORSION OF THE UTERUS.

The third ordinary meeting of the Midland Obstetrical and Gynaecological Society was held at the Medical Institute, Birmingham, on March 9th, with the President, Professor EWEN MACLEAN, in the chair.

Mr. BECKWITH WHITEHOUSE read a short communication on a case of acute torsion of the uterus. The patient, a nullipara aged 40, had been advised to have hysterectomy done for fibroids eight years previously, but had refused operative treatment. She was seized with acute pain and vomiting and became collapsed, with signs of internal haemorrhage. A tumour could be felt rising to the umbilicus, and there was free fluid present. On opening the abdomen the peritoneum was found to be full of blood, and a large solid tumour, purple in colour, was bleeding from a dilated vein on its surface. On delivery this tumour was found to be the corpus uteri greatly enlarged by an interstitial fibroid, and having undergone torsion through one complete twist at the level of the internal os. Supravaginal hysterectomy was followed by uneventful convalescence. Mr. Whitehouse pointed out that whereas most cases of torsion of the uterus occurred in old patients with tissues softened by senile atrophy, the present case was one of a woman of 40, the tissues of the uterus being firm and healthy.

Dr. C. D. LOCHRANE showed a specimen of sarcoma of the uterus and ovary from a woman of 41. A fibroid polypus had been removed from this patient twenty months previously, and a similar polypus at a later date. The uterus and both ovaries formed the specimen; the uterus was enlarged to the size of a four months' pregnancy by a soft submucous tumour, and the left ovary was much enlarged, whilst the right ovary appeared normal. The pathological report on the specimen stated that it was a spindle-celled sarcoma, probably of ovarian origin.

Mr. CHRISTOPHER MARTIN also showed a specimen of sarcoma of the uterus from a patient of 66. When first seen the uterus was the size of a three months' pregnancy, with a soft mass protruding through the cervix. This was removed, and on examination proved to be a spindle-celled sarcoma, and total hysterectomy was performed. The uterus was filled with a soft growth springing from the left wall, but showing very little sign of necrosis or of infiltration of the underlying uterine muscle. Mr. Martin pointed out that there were clinically two types of sarcoma of the uterus—that arising in the deeper layers of the endometrium and invading the myometrium very slowly, and that which occurred as a sarcomatous degeneration in a myoma and which by rapid invasion of the peritoneum led to a far graver prognosis.

Dr. C. E. PURSLOW showed a specimen of necrotic submucous fibroid removed by abdominal hysterectomy. When first seen, the uterus was enlarged to the size of a four months' pregnancy, and a necrotic mass occupied a dilated cervical canal. This was removed, but rapid recurrence of haemorrhage revealed a similar condition in the cervical canal a few weeks later. The mass was again removed, the cervix and vagina cleaned, and then abdominal hysterectomy performed. Dr. Purslow asked for comments on the procedure and technique to be adopted in such cases. The specimen excited considerable interest. It was thought by Mr. WHITEHOUSE and Mr. FURNEAUX JORDAN to look like a sarcoma, and was referred to the Pathological Subcommittee. Mr. Whitehouse thought that in these cases, after removal of the necrotic fibroid, the uterine cavity should be cleansed by packing with eusol solution for some days before proceeding to hysterectomy.

Dr. LOCHRANE also showed a specimen of primary carcinoma of the appendix removed from a woman aged 25 as a "chronic appendix, possibly tuberculous." The pathological report stated it to be a columnar-celled carcinoma. Three months later the abdomen was opened with the intention of resecting the portion of bowel involved, but no signs of recurrence being present the operation was not proceeded with.

Dr. LOCHRANE showed skiagrams of a ureteric calculus, and a curiously barbed calculus. There had been no haematuria during a history of renal colic extending over eight years, and the ureteral catheter had been passed up to the renal pelvis with ease, presumably passing between two of the spurs on the calculus.

THE Third Congress on Diseases of the Alimentary Canal will be held on April 28th and 29th at Homburg. Cholelithiasis and the relations between disturbances of the circulatory and digestive systems will be the principal subjects discussed.

THE Japanese Ambassador at Vienna has presented a sum of 6,500,000 crowns to Vienna University as a personal donation to relieve the financial straits of the University, and, it is stated, as a tribute to the scientific work that is being done there in spite of unfavourable circumstances.

Reviews:

THE FORM AND FUNCTIONS OF THE CENTRAL NERVOUS SYSTEM.

It is difficult to write of the anatomy of the nervous system without close reference to its functions. Professor TILNEY and Dr. RILEY have carried the concept of the interdependence of anatomy and physiology to its logical conclusion in their new work, *The Form and Functions of the Central Nervous System*.¹ The basis of the book is essentially anatomical, as one would expect from the previous records of its writers and its sponsorship by Professor GROSS HUNTINGTON. This attitude is more in keeping with the British school of neurology than is much American writing, which has latterly tended more and more towards the analysis of function alone. Perhaps a greater preoccupation with the essential structure and fundamental workings of the central nervous system might have acted as a healthy check or corrective on much speculative work. It is a pleasure, then, to have to deal with so substantial a work as this. And substantial it is, for it contains upwards of one thousand royal octavo pages. The design is bold, the plan excellent, and the execution creditable. As a matter of fact the authors have set themselves so huge a task that the attainment of a level so uniformly high is remarkable. Few signs of weariness are manifested, although the labour of writing a book which begins with the minute structure of the various types of nerve cell, embraces the anatomy and functions of the spinal cord and ascending levels, to finish with speculations on the functions of the frontal lobes, must have been enormous.

That a physiological process must have an anatomical basis is a self-evident truth, and that alterations in, and expansions of, function must be accompanied by changes in anatomical structure and connexion is also true. The need for changing plans and patterns to meet changing functions is well illustrated by the authors, and their remarks on comparative physiology in their explanations of comparative anatomy are not the least interesting feature of the book. He would be rash who would say that these speculations are always right, yet we owe the authors a debt for having stated a case, if for no other purpose than that later investigators should have something positive with which to disagree.

It is implied that this work is intended to be a textbook of the structure of the nervous system and its actual application to clinical medicine; so far as the need for such a guide is felt by medical students, this certainly is not the book for them. It is far too large for their purposes, but for reference it will be valuable, and it is in this that its importance lies. The more detailed study of the essential structure and plan of the central nervous system is a crying need of to-day. If every person engaged in the study of the psychical faculties and of behaviour could be compelled to learn the anatomy and fundamental functions of the central nervous system on some such scale and plan as is set out here, more sober work would result. Sobriety is, indeed, the watchword of this book.

The sections on the spinal cord and medulla are particularly well done. The spinal segments are illustrated in an original manner, Dejerine's distribution being followed. The syndromes of the spinal cord are well illustrated—sometimes necessarily by rare cases, such as primary lateral sclerosis. In the chapters on the cerebellum the authors express a strong opinion in favour of the theory of localization of function. They perform a service by printing the schemata of Elliot Smith, Bolk, and Van Rijnerk of the subdivisions of the mammalian cerebellum. These are thus easily compared with one another and with Mills and Weisenberg's diagrams of function in the human cerebellum. We should have expected fuller reference to Bárány's work in a book of this size. However, the index or pointing test is described, and a synopsis given of his deductions on the cerebellar areas associated with various muscular actions. The views of Tilney and Lambert on the synergic unit are stated at some length, but the addition of some tracings and photographs would have considerably strengthened the case for them. After the detailed discussion on localization we turn to the chapter on the cerebellar syndrome with great interest, hoping to find some illuminating histories of cases. We

receive not bread but a stone. The syndrome of cerebellar agenesis of Nonne is fobbed off on us, and we feel a little aggrieved.

It is impossible to do justice or even to refer to all the sections in so monumental a work, but we may remark that what the authors have to say on the pituitary syndrome is disappointing, and a not entirely convincing pineal syndrome is sketched. The various clinical pictures believed to be associated with disease of the thalamus and basal ganglia are stated, and the anatomy of these regions is well described. In relating the methods by which our knowledge of cerebral localization has been attained no mention is made of Elliot Smith's procedure, and Campbell's diagram is preferred to his and to that of Brodmann. It is curious also to see Campbell's figure of functional localization in the motor area chosen instead of the later figures of Sherrington. We do not object to Campbell's figures nor belittle their value; still, in a book where space has hardly been a consideration, it would have been well to have shown those of others as well.

It will readily be realized that the authors have attempted a herculean task. To keep a balance between minute structure, embryology, anatomical connexions, physiological significance, and the syndromes of disease is an undertaking of the most difficult order. The failures of the book are undoubtedly due to the oversteering, the overaccentuation, of one part at the expense of the rest. These faults are particularly obvious in the chapters on the hemispheres. An opportunity for a majestic survey of the gathering together and final elaboration of all the work done by the lower levels is here afforded, but the result is meagre.

We would not leave the book thus in what might seem an unfriendly spirit. For whilst we have dwelt upon some deficiencies we are not unmindful of the excellence of many parts. Those who work on the anatomy and the functions of the nervous system, those who study its diseases, are unquestionably debtors to Professor Tilney and Dr. Riley for their great labours, and will feel no little gratitude for the courageous way in which they have grappled with their huge task.

DERMATOLOGY.

Two well-known textbooks of dermatology have recently registered new editions: that of Stelwagon has now attained its ninth, while that of Norman Walker has reached its seventh. The appearance of the new STELWAGON² reminds us of the loss dermatology sustained by the death of its talented author; he died suddenly of angina pectoris while he was beginning to make preparations for the production of the present volume. The burden was ably taken up by his friend and colleague H. K. GASKILL, to whom we owe the successful completion of an onerous task. He has not materially changed the plan of this, one might almost say, classical work, but he has eliminated some of the older and superseded matter to make room for more recent investigations, and he has fully maintained one of the features which have always made this textbook so valuable—namely, the meticulous fullness and exactitude of the references. It is almost appalling to think of the amount of labour that has been so ungrudgingly spent on the collection and collation of dermatological literature for inclusion either in the main body of the text or in the voluminous footnotes which are to be found on well-nigh every page. The new Stelwagon is not so much a textbook as a dictionary of dermatology—a dictionary, moreover, in which, so far as a mere reviewer can ascertain, no entry of any importance is omitted. For specialists and for those who are already familiar with the elements of the subject this is an invaluable volume, and one which they should make a point of possessing. For students its value is not so certain; the presentation of the subject with such amplitude and elaboration might be calculated to discourage the youthful seeker after knowledge, and he might be overcome by the complexity of the pictures displayed to him. He should try something easier first, and will turn later on to the stronger meat of Stelwagon with an appetite that will assuredly be satisfied. As regards the get-up of the volume we have little but praise. The printing is good; there are no obvious typographical errors. It is well and copiously illustrated, principally by photographs, and in some cases by diagrams; a few of the plates are in colour. As ever, the

¹ *The Form and Functions of the Central Nervous System*. By F. Tilney, M.B., Ph.D., and H. A. Riley, A.M., M.D. Foreword by George S. Huntington, Sc.D., M.D. London: H. K. Lewis and Co., Ltd. 1921. (Roy. 8vo, pp. 1620; 763 figures. 70s. net.)

² *A Treatise on Diseases of the Skin for Advanced Students and Practitioners*. By H. W. Stelwagon, M.D., Ph.D., and H. K. Gaskill, M.D. Ninth edition. Philadelphia and London: W. B. Saunders Company, 1921. (Roy. 8vo, pp. 1313; 401 figures, 23 plates. £2 10s.)

coloured illustrations are at once the attraction and the disappointment of books on skin diseases. The medical public will have them, but they are seldom satisfactory. They are not very good even in the present instance. Finally, we may add that, considering its size, the number and excellence of the illustrations (even including the coloured ones), the binding and general format, this book, judged by modern standards, is cheap at its price.

Dr. NORMAN WALKER's *Introduction to Dermatology*³ affords a striking contrast to Stelwagon's treatise. Founded, as the author states, on his own lectures, it is essentially a book for students. It is clear, precise, and definite, not overloaded with detail, and although it has grown quite a lot during its progress through successive editions it still remains only about one-third of the size of Stelwagon. In stating that it is essentially a book for students we do not mean to discourage more advanced readers. Practitioners and specialists will alike find much to interest and stimulate them within its covers. It is an expression of Dr. Norman Walker's very energetic and distinctive personality, and is written with attractive raciness of language. Sometimes, indeed, he finds the English inadequate for his needs and is compelled to relapse into Scottish, as in the use of the word "kenspeckle," which, however, in a footnote he is good enough to explain means "having so singular an appearance as to be easily recognized." As would be expected in a work possessing these characteristics the allotment of space among the various divisions of the subject seems sometimes rather capricious. The most interesting and fullest chapter is that devoted to dermatitis of various causes, especially "dermatitis venenata" and "autophytica," subjects that have always attracted the author's attention in a high degree, and on which he has written in our columns. On the other hand, his description of the rashes and treatment of syphilis is, one might almost say, meagre, being limited to about seven pages only. To some extent he anticipates this criticism by prefacing his remarks by the statement that "special monographs or textbooks on surgery must be consulted" for a description of the disease as a whole; but, after all, syphilis is disease which attacks the skin at some time in every case, and the diagnosis of cutaneous syphilis from other conditions is one of the commonest and most important problems that can be presented, either to the dermatologist or the general practitioner. Moreover, there is one sentence in his few remarks on the treatment of this disease that really ought not to go unchallenged. Speaking of the treatment of the primary stage, he says: "Two or three doses (of 0.5 of a gram of salvarsan or one of its substitutes) given at intervals of ten days may sometimes be all the treatment that is required." Is not this a rather dangerous doctrine for so high an authority to promulgate? On the other hand, the chapter on lupus and tuberculosis of the skin is full and good. A timely word of warning is given against the overuse of x rays, which are too liable to be followed by carcinoma, and the author is more in favour than most dermatologists of using old tuberculin, but in rather an unusual form—namely, as an ointment rubbed into the lesions. On the other hand, he does not believe very much in excision, although there is a growing tendency to regard this as one of the best methods of dealing with lupus when practicable. Another point whereon Dr. Norman Walker differs from many of his colleagues is as regards the contagiousness of alopecia areata. He holds that there is sufficient evidence to justify the medical officer of a boarding school in refusing to allow a case of alopecia areata to remain there while being treated, although he would not exclude a case from a day school. The book is profusely illustrated, and there are a large number of coloured plates. We gladly admit that these are more successful than usual, and in many instances give a very good idea of the clinical appearances of the diseases illustrated. The book is convenient in size, easy to handle, and attractive to read, and may confidently be recommended to students, practitioners, and dermatologists.

The appearance of the second edition of Dr. HALDIN DAVIS's book on *Skin Diseases in General Practice*⁴ is proof of its merit. The method of approaching the subject is novel, and

if Sabouraud's *Dermatologie topographique* be excepted, is probably dissimilar from that of any other textbook on dermatology. What may perhaps be termed a regional classification has been adopted—that is, the eruptions are described as they affect certain areas of the body. The value of this arrangement is evident when we remember how regularly most skin diseases select certain areas. By this regional plan the practitioner is informed what diseases may be expected to affect a certain area. Did the author limit himself to a rigid system of this sort many of the advantages would be lost, but he has been careful to complete the symptomatology and thus present a scientific and intelligent account of disease. The indications for treatment are clear and thorough, and include all methods available to a well-equipped physician. The illustrations are many, some in colour, and these add completeness to the book. Thus the second edition comes up to the high standard of the first. The author is to be congratulated upon his admirable little treatise.

The fourth edition of *Diseases of the Skin*,⁵ by Dr. R. L. SUTTON, is considerably larger than its predecessors; it now contains over 1100 pages. Although some new subjects have been added, such as nocardiosis, dermatitis dysmembrhoeica, and neurotic excoriations, the general plan remains much the same, the text having been expanded here and there and revised where necessary. The author expressly states that foreign contributions have in this edition received fuller consideration, and this is borne out by examination of the well-selected bibliographies appended to the different sections. American dermatology occupies a high position, and the book under review is a worthy representative of the scientific medicine of the author's country. It is well illustrated and produced, and conforms to the high standard of the previous editions.

ZOOLOGY FOR STUDENTS.

It may be conceded at once that Professor J. GRAHAM KERR'S *Zoology for Medical Students*⁶ is an excellent book, written in a refreshingly original manner. The first difficulty to be overcome in writing an elementary textbook of zoology is to present the phenomena of life as an orderly sequence, so that facts appear to the student's mind to be in some way related. We believe that one or two of the recent textbooks, Professor Kerr's among them, have succeeded in making an orderly presentation, and that the earlier textbooks were not so successful. Zoology, unless taught with extreme care, is apt to be regarded by first and second year students as a series of isolated facts, and to be memorized in the same way that most of us memorized our Homer. The second great difficulty is to present fact in terms of function without recourse to knowledge which is not in the possession of the elementary student. Professor Kerr has successfully surmounted these difficulties, and will hold the student's attention all the more surely because groups have been illustrated very frequently by species of economic importance. We cannot call to mind any book written from the point of view of the pure zoologist in which such up-to-date knowledge of economic problems is displayed. No really important advance in our knowledge of the protozoa, worms, and insects harmful to man has been omitted; organisms which destroy crops and garden produce are not so generally mentioned.

Professor Kerr's facts, then, are well selected and well presented. We wish we could approve the general plan of his book. We understand from the preface that it represents lectures in zoology delivered to first-year medical students of Glasgow, and that the course in zoology lasts no more than ten weeks. The reviewer would have been a proud man if he had mastered the material in this book by the end of his second year. Its 475 pages of text seem to carry the reader a great deal farther than any pupil of average ability could go, and to introduce him to a vast number of types, admirably chosen we admit, which he will be unable to remember. The book contains too much, and the excess of matter is very unevenly distributed. The author is a teacher of experience, and his results are good; he has a perfect right to divide up his space as he sees fit; but we think he is mistaken in

³ *An Introduction to Dermatology*. By Norman Walker, LL.D., M.D., F.R.C.P. Seventh edition. Edited with W. Green and Sons, Ltd. 1922. (Demy 8vo, pp. xviii + 356; 54 plates, 52 figures, 25s. net.)

⁴ *Skin Diseases in General Practice*. By H. Davis, M.R. B.Ch., B.A.Oxon., F.R.C.S. Eng., M.R.C.P. Second edition. Oxford Medical Publications. London: H. Kewley and Hodder and Stoughton. 1921. (Demy 8vo, pp. 357; 73 figures, 8 plates. 25s. net.)

⁵ *Diseases of the Skin*. By R. L. Sutton, M.D. Fourth edition, revised and enlarged. London: H. Kimpton. 1921. (Sup. roy. 8vo, pp. 1132; 569 figures, 11 plates. 55s. net.)

⁶ *Zoology for Medical Students*. By Professor J. Graham Kerr. London: Macmillan and Co. 1921. (Demy 8vo, pp. x + 495; 199 figures. 25s. net.)

writing eleven pages to sponges, forty-five to fishes (excluding Amphioxus and the Lampreys, which are treated fully), and only twelve to the Mammalia. There is no description of the anatomy of any particular animal; and the student who has no concrete knowledge of his rabbit can scarcely appreciate the lucidity with which the general characters of the mammalia are discussed. The omission of the anatomy of some chosen type is a doubly serious loss to the medical student, because in his second year he will presumably devote six months to a human arm or leg, and to following the courses of the radial artery, but he will not have handled the mammalian heart, and he may possibly have no knowledge of any heart higher than the frog's.

We should like to see the liver fluke banished from all elementary textbooks. Its anatomy is diabolical and its importance as a parasite of man very small; it has, we admit, great historical interest. In its place we would put *Spitherechis*, a widely distributed fluke, commonly found in the cat, and of some importance as a parasite of man himself. This organism has a simple anatomy and a known life-history; it appears to be an ideal fluke for the student.

The figures in Professor Kerr's book are excellent. They are all good line drawings, well conceived, but admirably simple. The index is good, and the price not exorbitant.

THE HISTORY OF ELECTROTHERAPY.

AN essay on the *History of Electrotherapy and Diagnosis*, by Dr. HERON A. COLWELL, assistant radiologist to King's College Hospital, is a scholarly account of the development of the use of electricity as a curative agent. As the author starts with the use of medicinal springs, which are believed to derive a part of their efficacy from the presence of radioactive substances, and treatment by static electricity as obtained from a living animal—namely, the torpedo fish—it is evident that the method can be traced back to far distant times. After this somewhat remote introduction the various steps in the development of our knowledge of electricity are traced, and amongst other things it is explained that Gilbert's work, *De Magnete*, published in 1600, laid the foundation of modern conceptions of electricity, and that he was the first to use the term "electric"; that the next great step forward was the making of a primitive electrical machine by Otto von Guericke about the year 1650; and that Gallabert, Professor of Physics at Geneva, must be regarded as the first scientific electro-therapist, since it was in 1747 that he attempted to produce muscular contractions by electricity with a view to the exercise of individual muscles, and thus preceded Duchenne by about a century, although it is undoubtedly that the foundation of modern electro-therapeutics is due to the latter.

In writing this book Dr. Colwell has adopted the plan of arranging his material in the order of priority, and thus it is easy to follow step by step the developments from remote ages down to the present time. He takes each authority in due order, quotes his work, indicates its influence on future developments, and in most cases inserts illustrations of the various writers and of their apparatus. It is evident that an immense amount of care and trouble has been taken to achieve completeness, and probably nowhere else could this vast amount of historical information be so easily obtained. The illustrations are a prominent feature, and all are of excellent technical quality. They consist mainly of portraits of the famous men of the past who have by their discoveries advanced electrical knowledge, and of plates showing the somewhat primitive electrical apparatus used by them in making these discoveries. The author can be congratulated on having written a book of absorbing interest, which is at once a valuable historical record and a book of reference, which should find a place on the shelves of all those who are interested in his subject.

THE TRIAL OF STEINIE MORRISON.

IN our issue of September 17th, 1921, page 447, we reviewed Mr. Houghhead's book on the trial of Burko and Hare. The extraordinary crimes with which those criminals were charged were of considerable medical interest. Another volume of the same series of *Notable British Trials* is now before us,

An Essay on the History of Electrotherapy and Diagnosis. By Heron A. Colwell, M.B., B.S., M.R.C.S., D.P.H. London: William Heinemann (Medical Books), Ltd. 1922. (Demy 8vo, pp. xiii+180; 115 illustrations, 17s. 6d. net.)

The Trial of Steinie Morrison. Edited by H. Fletcher Moulton, B.A., LL.D., of the Middle Temple, Barrister-at-law. Notable British Trials Series. London and Edinburgh: William Rodge and Co., Ltd. 1922. (Demy 8vo, pp. 282; 10 illustrations. 10s. 6d. net.)

dealing with the trial of Steinie Morrison for the brutal murder of Leon Beron in 1911. Although no important question of forensic medicine arose, and such medical evidence as was given had little influence on the result, this trial cannot fail to be of interest, not only on account of the mystery surrounding it, but still more because of the strange world of Jewish aliens in which the victim and the accused, and so many of the witnesses in the case, were shown to have lived.

The murder took place on Clapham Common, but the other scenes of the drama were enacted in Whitechapel in the modern ghetto, close to what was formerly called Petticoat Lane. The public at this time was more than usually interested in foreign Jews and anarchists on account of the recent murders of policemen in Houndsditch, and the Sidney Street siege, which had taken place just before this trial, and in the neighbourhood where nearly all the dramatic personae lived.

The victim was considered a capitalist. He wore a valuable gold watch and chain; but his income (derived from house rents) did not exceed ten shillings a week, and for the five years he had been in England he seems to have lived a life of complete idleness, spending most of his days from breakfast to closing time in a small Jewish coffee house, where his expenditure averaged not more than fifteen pence a day. The accused was a Russian Jew, a man of fine physique, and a convict on ticket-of-leave, who had more than once been convicted of burglary. He claimed to make a living by selling cheap jewellery, but there was no foundation for the claim except his own statement, and he failed to account satisfactorily for the money which was in his possession after the murder.

The alien witnesses—some of whom knew little or no English—appeared one and all to have very rudimentary ideas of truth, so that, as Mr. FLETCHER MOULTON, the editor of the book before us, remarks, it seemed that the court, on the Indian precedent, "should approach all evidence in a spirit that if verbal it is perjured, and if written forged, but above all should avoid being prejudiced against the merits of a party's case merely because that case is supported by false evidence." Most of the witnesses appeared to have had small visible means of subsistence. One of them described himself as "a gentleman of independent means," but those means were shown to be about fifteen shillings a week, and Rowton House was his place of residence.

The case for the Crown rested largely on the evidence of identification given by three cabmen who were alleged to have driven the prisoner to and from Clapham Common. Such evidence seems to us, as it probably did to the judge, of very doubtful value, when we consider that the witnesses only saw the man at night, for a very few minutes, and in no circumstances which would tend to direct particular attention to him, and, moreover, that his likeness had appeared in the daily papers before the identification took place.

Whether Steinie Morrison was guilty or not, it remains a mystery how the humdrum middle-aged Leon Beron was induced to take a long cab drive from Whitechapel to Clapham Common in the small hours of New Year's morning. The marks on the cheeks of the dead man and the recent events in the East End suggested to many people that the crime was political. There was, however, no evidence that Beron or Morrison had anything to do with any secret society or plot, and probably the murderer made these cuts or scratches with the intent to put the police on a false scent.

Mr. Justice Darling presided at the trial with conspicuous ability and fairness. In his summing up he almost suggested that, had it been permissible, a verdict of "Not proven" would have been appropriate. The jury, however, found the prisoner guilty of wilful murder. The conviction was upheld by the Court of Criminal Appeal. The Home Secretary at the time was that "man so various" (*testis* Lord Robert Cecil), Mr. Winston Churchill. One of his various solves had lately astonished and amused the civilized world by attempting to arrest two alien criminals in an East End slum with the help of two Horse Artillery guns and a company of Foot Guards. A more prosaic and common-sense compartment of his brain decided to commute the death sentence on Morrison to penal servitude for life. Considering all the circumstances, we cannot but approve of his action. During the ten years to which Morrison's life sentence extended, he was, trouble-some and refractory; he starved himself for long periods, and died last year, probably weakened by his fasts, protesting his innocence to the last.

NOTES ON BOOKS.

WE mentioned some time ago the *Quarterly Cumulative Index to Current Medical Literature*, founded upon the lists published in the *Journal of the American Medical Association*. It will be remembered that the April number of each year indexes journals issued in the first quarter of the year; the July number supplements this by indexes to journals published during the second quarter, and so on. We have now received the volume for the year 1921. It contains lists of new books; in one they are given under the names of the authors, alphabetically arranged; in the other they are classified according to subjects. This last is a very useful feature. There is also a list of documents issued by the Government of the United States.

The second edition of Professor ERBEN's textbook on the diagnosis of simulation of nervous symptoms⁹ gives an account of the thousand and one aches, pains, disabilities, paralyses, and so forth that are put forward by the malingerer, and describes the lines on which a true diagnosis is to be reached without doing possible injustice to the patient owing to failure to detect the presence of organic diseases that may produce very similar symptoms. The subject-matter is well arranged and indexed; there appears to be no mention in the book of the simulation of blindness or deafness.

The second edition of the *Treatise on Fractures*,¹⁰ by J. B. ROBERTS and J. A. KELLY, is somewhat enlarged by the introduction of additional illustrations and by the more detailed consideration of fractures in military and industrial practice. By the judicious use of radiographs and diagrams the authors have succeeded in giving in a most vivid manner a representation not only of the various forms of displacement met with in fractures, but also of the various methods by which fractures may be reduced and kept in good position. It is perhaps not too much to say that the book is one of the best textbooks on the subject, and should prove of the greatest use to the student and general practitioner.

⁹ *Diagnose der Simulation nervöser Symptome auf Grund einer differentialdiagnostischen Betrachtung der einzelnen Phänomene*. Von Prof. Dr. S. Erben. Zweite, vielfach ergänzte und erweiterte Auflage. Berlin and Vienna: Urban und Schwarzenberg. (Sup. roy. 8vo, pp. 272; 3 plates, 25 figures. M.56; bound, M.75.)

¹⁰ *Treatise on Fractures*. By J. B. Roberts, A.M., M.D., F.R.C.S., and J. A. Kelly, A.M., M.D. Philadelphia and London: J. B. Lippincott Company, 1921. (Medim. 8vo, pp. 725; 1631 illustrations. 45s. net.)

TEETH, HEALTH, AND THE HOME.

USING figures of a report made in 1912 by a school medical officer to his county council, Mr. E. C. Rhodes has endeavoured to assess statistically the relation between teeth and health in children. His methods are described and his results are detailed in a report published from the Galton Laboratory.⁵ Professor Karl Pearson in a preface tells us that observations designed to secure better data are in progress, but that meanwhile the purpose of this first paper will have been fulfilled if it demonstrates that there is a wide field for valuable co-operation between an institute such as the Galton Laboratory and public bodies making a necessarily rapid survey of their child population but having little leisure for research.

That there is this wide field and the possibility of valuable co-operation is abundantly evident both from the nature of the questions raised and from the masterly manner in which Mr. Rhodes has dealt with figures that at first sight seemed to offer insuperable discrepancies. The observations of five different doctors had to be investigated, and it was found that their standards differed too much to render it possible to reduce them all to a common standard. Two pairs could so be reduced, and the means by which this was done afford a striking example of good statistical work and of impartiality in handling figures. As the large differences of standard between some of the doctors made the effective treatment of the whole material on a common basis impossible the results were less reliable than they would otherwise have been, and the author seems fain to regard his work rather as showing what may be done by statistical methods, and the faults of the usual methods of collecting data, than as affording definite conclusions.

Mr. Rhodes has correlated the condition of the teeth with weight, nutrition, anaemia, condition of nose and throat, as

factors giving an indication of the child's health; and with cleanliness of body and father's employment as factors giving an indication of home conditions. The figures were drawn from reports on boys and girls from 12 to 14 years of age, and the conclusion reached is that, on the whole, there is nowhere any very high degree of correlation between bad teeth and any other character examined. The author realizes that the data collected by the medical inspectors were not collected with a view to statistical inquiry, but pleads—and we heartily support him—that if they were their value from the standpoint of social hygiene would be raised out of all proportion to the greater trouble involved. Observers should work to a national standard—a point to which Mr. Rhodes suggests the Ministry of Health might well give its serious attention. Probably the setting up of such a standard will not be easy. We think, indeed, that Mr. Rhodes himself is at fault in his estimate of when a tooth is carious. He says (p. 42): "It is generally understood that before caries in a tooth can set in a preliminary rotting of the tooth must have followed the chemical changes which take place in the remnants of food lodged in the interspaces and crevices of the tooth." By "preliminary rotting" we imagine he means rotting of the enamel, reserving the term "caries" for destruction of the dentine. To the dentist rotting of the enamel is caries as much as rotting of the dentine; and if the dentist's standard were adopted clinical experience suggests that so large a number of carious teeth would be found in all sorts and conditions of children that healthy and unhealthy would be judged equally carious. If, however, note were taken only of the second and third stages of decay—that is, caries of the dentine—abscess being of frequent occurrence in the third stage, then the clinician will be disposed to believe that a definite relation between caries and states of ill health (anaemia, loss of weight, malnutrition) would be found. It may also be suggested that since treatment of the teeth of school children resolves itself largely (and rightly so) into extraction, some account should be taken of teeth extracted for caries, or at least of those recently removed.

Viewing the matter from another standpoint—the influence of heredity—Mr. Rhodes suggests that it would be of interest to find out whether any association exists between the state of the parents' teeth and those of the children. His work shows that the degrees of association between the state as to caries of the teeth in children of 12 to 14 and their general health and home environment are but slight, being about 0.1 in the scale of the correlation coefficient, while the relationship between parent and child for many physical characters is 0.5. If, then, the dental association were found to be about 0.5, heredity might be claimed as an important factor in the occurrence of dental caries.

Mr. Rhodes also examined the association of weight with father's employment, of nutrition with weight, and of nutrition with anaemia. Of these, nutrition and weight are the only pair of factors discovered in the whole investigation that yield a high correlation coefficient, but he notes that the medical judgement of nutrition may itself have been based on weight, or at least on size and plumpness. The other two show a positive sign of no great intensity.

As has been already noted, on account of insufficiency of data the results of Mr. Rhodes's work cannot be accepted as conclusive, but if it serve the purpose of drawing attention to the need and value of standardization in the method of making and recording observations, his publication of his report will have been amply justified.

"CINEMATOGRAPHS AND VIVISECTORS":
A FLANK ATTACK.

LAST week (March 28th) the *Times* published an article in large type, headed "Cinematographs and Vivisection: How Pain can be Saved," and also a leading article which began by the statement that "The reflective layman hesitates before the dilemma raised by painful experiments on animals." The article suggested the use of cinema films for the recording of experiments on animals, especially for teaching. "In this matter," the article said, "the average layman is not prepared to follow those ardent physiologists who claim or have claimed that even painful experiments on living animals are a legitimate part of medical training. We may agree in theory that they add to the vividness of a lecture and impress on the memory details that diagrams and verbal descriptions

⁵ *On the Relationship of Condition of the Teeth in Children to Factors of Health and Home Environment*. By E. C. Rhodes, B.A. Cantab. London: Cambridge University Press; H. K. Lewis and Co., Ltd.; and W. Wesley and Son, 1921. (Roy. 4to, pp. viii + 50; 4 diagrams. 9s. net.)

have vague. But, so far as this country is concerned, it is now generally agreed that the end does not justify the means." The implication in both articles is quite clear; it is that painful experiments are unnecessarily performed, and are performed to illustrate lectures or demonstrations to medical students. That this impression is, in fact, conveyed is fully confirmed by a letter from the Duchess of Hamilton published in the *Times* of March 30th. "To all humane people," the Duchess says, "the thought of their sons and daughters, being trained by lectures given over a tortured creature must be abhorrent—the one drawback to entering that most noble of professions, the art of healing." Now the implication is not true, and the *Times* ought to have known that it was not true, since, apart from other sources of information easily available, the truth can be ascertained by a short study of the Aet. The position has been well explained by Professor Starling in a letter published in the *Times* of March 31st; he has placed a copy at our disposal, and we cannot do better than reproduce it in full:

To the Editor of the "Times."

Sir.—My attention has been called to an article entitled "Cinematographs and Vivisection" in your issue of March 28th. Either ingeniously or ingenuously your correspondent contrives to convey the totally false impression that painful experiments may be and are used for purposes of instruction, and that these form an ordinary means of research for the advancement of physiological knowledge. This untrue, generally conveyed by implication rather than by direct statement, is a stock-in-trade of the professional lecturer of the antivivisection societies. May I be allowed here to state once again what are the facts?

No painful experiment is ever performed for the purpose of teaching or demonstration. The occasions on which any infliction of physical pain is necessary in an experiment for the advancement of physiological knowledge must be very rare. Indeed, at the present time I cannot think of any case in which such a contingency could not be avoided. During the last thirty-three years I have probably performed more so-called vivisections than any physiologist in this country. Never during these years have I inflicted pain on an animal. Our whole life is devoted to the study of the working of the body in order to diminish the sum total of human and animal suffering, and we acquire thereby a horror and detestation of pain, which are perhaps exaggerated, but are more real than the horror-fed sentimentalism of the average antivivisection audience.

With regard to cinematography as a method of teaching and research, this is a subject to which I have devoted much time and attention. Though its applicability is at present extremely limited, there is no doubt that the method will be very useful for the study and analysis of certain forms of movement. But it is not suited for the study or teaching of other functions of the body in which movement does not form the essential feature, so that it can never be used to the exclusion of actual experiments. Nor is this desirable. The great object of experimental demonstration is to put the student's knowledge into three dimensions and to correct the purely verbal and two-dimensional ideas he obtains from the study of books and pictures, or even films. Who among your readers would choose to be operated on for appendicitis by a surgeon whose only acquaintance with the operation had been derived from pictures and moving films?

With part of your correspondent's last sentence I am in complete agreement—namely, that on scientific grounds there is a large field for the further employment of the cinematograph. But it is not true that humanitarian grounds are also involved; humanity demands the fullest development of the experimental method for the advantage both of man and of the lower animals. Twenty thousand dogs are killed painlessly every year in the Dogs' Home, Battersea, and no one is benefited. A few hundred are killed equally painlessly in the physiological laboratories of this country with, as a result, the remarkable advance in physiological knowledge and in the control of disease which during the last thirty years have contributed so much to the benefit of man and the alleviation of suffering.

I must apologize for troubling you with this restatement of facts which must be well known to the vast majority of your readers.—I am, Sir, your obedient servant,
E. H. STARLING.

THE HOSPITAL POLICY OF THE LABOUR PARTY.

The Labour party has prepared and issued a statement of its policy in regard to public hospitals. The document is a pamphlet of twenty closely printed pages, concluding with a summary, which amounts in effect to a policy set out in the following thirteen recommendations:

1. The Labour party, recognizing the importance of health to the individual and national well-being, considers that all hospitals, both general and special, together with allied institutions, should be so organized under one authority as to form the foundation of a complete hospital system for the nation with sufficient accommodation to deal with all cases requiring institutional treatment.
2. It would establish treatment centres in outlying districts, local or cottage hospitals in the smaller towns, one or more county hospitals conveniently situated in each public health area, and national hospitals in London and Edinburgh and other university towns.
3. It would organize intimate co-operation between all the hospitals in each public health area and also between them and the nearest national hospital. It would make arrangements for easy and rapid transference of patients from one hospital to another according to the nature and requirements of the case.
4. It would organize intimate co-operation between the medical staffs of the various hospitals, and also between them and general practitioners, making the participation of the latter an essential feature of the hospital scheme.
5. It would provide the Health Authority with sufficient beds under their own control to deal with all patients for whom they have already undertaken the responsibility. (Patients suffering from tuberculosis or venereal diseases, children from the school clinics, mothers and infants from the maternity and child-welfare centres, and adults from the National Health Insurance Schemes.)
6. It would introduce the necessary legislation for the transference of the Poor Law Institutions from the Guardians of the Poor to the Local Health Authorities, thus placing at their disposal many beds now vacant. It would remodel these infirmaries, where necessary, equipping and conducting them in every way on the lines of the best existing general hospitals.
7. It would give voluntary hospitals the option of being taken over by the Health Authorities entirely, or of receiving grants from public funds conditional on efficiency. The Local Health Authority should be represented on the Boards of Management, and, though remaining on an entirely voluntary basis, such hospitals should work in co-operation with the public hospital.
8. It would relieve pressure on hospital beds in the cities and towns by acquiring convalescent homes in the country, into which should be admitted cases of threatened breakdown and patients no longer requiring hospital treatment, but not sufficiently recovered to return home.
9. It would establish free dental clinics connected with all hospitals, believing that supervision and treatment of the teeth are essential to health.
10. It would also arrange a scheme for visiting nurses and home helps in connexion with the hospital system, and lays special stress on the importance of the skilled supervision and after-care of patients who have recovered or partially recovered from an illness.
11. It would make all public hospitals free and open to everyone who would be likely to derive benefit from institutional treatment.
12. While doing this it would insist on the treatment offered being equal to that of the best voluntary hospitals in efficiency.
13. It would endeavour to forestall the necessity for so many hospital beds by a forward social policy generally, and in particular by establishing a "national minimum" in health and housing by abolishing all slums and undertaking a comprehensive housing scheme.

* *The Labour Movement and the Hospital Crisis.* A statement of policy with regard to hospitals. Published by the Trades Union Congress and the Labour Party, 32, Eccleston Square, London. Price 1s.

STRINGENT regulations regarding x-ray laboratories have been promulgated by the New York Board of Health. No person is to operate an x-ray laboratory, or to advertise that an x-ray laboratory is conducted, without a permit issued by the Board of Health; every x-ray laboratory must at all times be in charge of a qualified medical practitioner or other person whose experience and qualifications are satisfactory to the Health Department. Rules are also laid down for the safety of the operators and patients.

British Medical Journal.

SATURDAY, APRIL 8TH, 1922.

THE HOSPITAL POLICY OF THE LABOUR PARTY.

THE statement on policy with regard to hospitals which the Labour party has put out will be read with interest because it emanates from one of the important political parties, although opinions will differ as to its intrinsic merits. The policy it presents to the public is embodied in thirteen propositions, which are printed in full on the preceding page (570).

To these thirteen articles the reader will react according to his political sympathies. If he has a leaning to what is known as nationalization he will consider No. 1 a reasonable ideal, and will accept all that flows therefrom. If he has no such leaning he will still accept some of that proposition, at any rate to the extent of the assertion that "there should be sufficient accommodation to deal with all cases requiring institutional treatment." Articles 2, 3, 4, 8, and 10 are common ground for all those who have considered the necessities of modern medical work; statements to much the same effect have appeared in reports of the British Medical Association, in the Dawson Report, and in others less well known. The help of the Labour party in attaining the aim set out in the second part of No. 10 would be very welcome, but has not hitherto been given in any large measure. As to No. 13, the medical profession has been for fifty years insistent that steps should be taken to abolish old slums and to prevent the formation of new slums. Some will be disposed to ask for a definition of the phrase "comprehensive housing scheme"; even a passing glance at what has been going on during the last few years suggests that we are not altogether on the right lines, that either local means of communication must be improved to a degree hardly to be hoped, or that the policy of building two-story houses must be reviewed. On the whole it may be said that a cursory examination of the thirteen propositions as they stand suggests little material for criticism of them as a statement of their views on an important problem by the Labour party's advisers in hospital matters; that they have formulated their opinions is to their credit, and we are glad to know what these are, whether we agree with them or not.

So much can be said for the summary. If that were all the document might be received with thanks as an expression of opinion. But it is much more than that, and we scarcely remember reading a paper issued by a group of public men which contained more conflicting statements than this. It bears internal evidence that it is the handiwork of medical men—among them men engaged in hospital practice: it has few marks of labour—of the toiler in the field, the street or the workshop; it seems to be, in fact, less the expression of the opinion of the Labour party than of a small group of men of our own craft who are attached to that party. It might have been expected that these men would have made a simple and balanced statement of the conditions of hospital affairs which would have really helped those who look to them for guidance. We do not find this balance. We find instead statements almost effusive in praise of voluntary hospitals mixed with observations on the working of these same institutions which are at once depreciatory and misleading. The impartial reader of the report gets the impression that its compilers, with

a set doctrine before their eyes, had come to curse certain "voluntary" efforts, but, like Balaam, had been constrained to bless, even though at times the impulse to curse has triumphed.

The document begins with the statement, "At the present time, with rare exceptions, general hospitals are supported by voluntary contributions," and the term "general hospital" is used throughout as a synonym for voluntary hospital. The writers nowhere give any indication of a realization of the fact that the large institutions established as Poor Law infirmaries, which contain a greater number of beds than the voluntary hospitals, are in reality large general hospitals. To this point we shall recur when we come to the figures upon which the case for expansion is based. The remainder of the opening paragraph is a strange commentary on the chief recommendation of the report—that the one and only salvation for the hospitals of the country is State control and management—for the paragraph recites a long list of conflicting or overlapping public authorities which are at present responsible for hospitals, and indeed control a large majority of the hospital beds in the country. If the State has not contrived in all these years, with the hitherto unlimited resources at its disposal, to unify its own system of statutory hospitals, what advantage to the sick person will arise from the absorption into this welter of State hospitals of the voluntary hospitals, which are admitted in this report to attain an ideal standard of efficiency, even though "each is administered by its own committee of management" and "is a law unto itself"? No exception need be taken to the succeeding paragraph. It deals with the work of general hospitals (meaning the voluntary hospitals), and it concludes with the statement in large type: "A general hospital to-day is indeed an excellent example of the necessity for 'team work' and of the benefits that may be derived therefrom, and the policy of the Labour movement is to secure similar benefits for all, both within and, as far as possible, without the walls of the hospitals." The paragraph on the "Necessity of Hospitals to a Healthy Nation," despite the ambiguity of its title, has some good points in it; and we accept whole-heartedly a concluding statement that "good equipment, good nursing, easy access to all varieties of specialist help, and the best possible hygienic surroundings are essential in serious cases of illness." The recommendation concerning the relations of hospitals and general practitioners has been the policy of the British Medical Association for many years, but there is some doubt as to the meaning of the phrase, "It is equally important that general practitioners should have a recognized call on hospital consultants and specialists for help with patients of all classes who are being treated in their own homes." In view of the later recommendation that hospital benefit should be free to all and paid for out of the rates, we are inclined to suspect that this is a demand for free benefit of consultant and specialist for all—again as a charge on the rates.

It seems incredible that the paragraph on "Present Hospital Accommodation" should have been issued by any body purporting to represent two great organizations of citizens. "For the realization of these ideals very ample hospital accommodation is essential. Accommodation can best be reckoned by the number of hospital beds available for the treatment of general diseases and accidents; and it has been found on investigation that at the present time there are absurdly few in comparison with the number required to deal with the present population of Great Britain. In the United Kingdom there are 52,194 beds. . . . Taking 2½ beds per 1,000 of the population as the lowest possible minimum for the whole country, the number required for a population of 48 millions is 160,000, which shows a deficit of 107,906 beds." Those who penned this statement must have forgotten that there

are vastly more hospital beds in the country than those of the voluntary hospitals. Moreover, it is misleading to reckon "general hospital" beds as the sole criterion of accommodation. Fever hospital beds are just as much part of the necessary equipment, and should count in the total; any lack of these special beds, or others like to them, means an additional call on the "general hospital" beds. The figure given of 52,194 as the sole available accommodation in the country is absurd. In London alone there are more than this total. According to a return supplied by a public authority, London has over 52,700 beds, made up of fever hospitals, sanatoriums, Poor Law infirmaries, voluntary hospitals, and a number of smaller institutions. Of these, the Poor Law infirmaries provide 15,400, the voluntary hospitals coming next with 12,670. How much reliance can be placed on an argument or on a line of policy resting upon premisses such as the figures we have quoted?

We come now to what seems to us the worst feature of the document. The "Anomalies of the Voluntary System" are described in three pages with several subparagraphs. First, there is the correct statement that the voluntary hospitals were built and endowed by charity for the really necessitous poor, and that "they are now utilized to a great extent by the skilled artisan, and to an increasing extent by the lower middle and even the professional classes." So far as the second clause is true it is the inevitable result of the decrease in the indigent class and the increase in those who recognize the superior benefits of the voluntary hospitals and desire to partake of them. That this is technically a "hospital abuse" (unless the change be recognized in the conditions of admission of these new patients) is also true, and for that difficulty the British Medical Association has been at pains to indicate the remedy. It is further stated that an appointment on a voluntary hospital has a "monopoly value," so that "the number of appointments is jealously guarded, with the result that all big hospitals are badly understaffed." We should like to see the data on which this statement is based. Turning to the *Medical Directory*, we find that the London Hospital, with 922 beds, has a total active medical staff of no fewer than 85, of whom 27 are whole-time residents; this does not include clinical assistants, whose work is by no means negligible; nor does it include the retired "consultants" and the service given by students. Taking a small general hospital—the West London Hospital, with 160 beds—we see that it has an active staff of 42, of whom 7 are whole-time residents; from the enumeration clinical assistants and "consultants" are excluded. If this be understaffing, what are we to think of the State hospitals? The same directory gives the records of the Poor Law infirmaries: we find Hackney Union Infirmary has 910 beds and a staff of 5 qualified practitioners, whilst St. Giles, Camberwell, with 828 beds, has a staff of 6; the other infirmaries do not show so well as these. It is true that these are whole-time residents and that on occasions outside practitioners may be called into consultation; also that there are no out-patient departments; but what is that in comparison with the staffing of the voluntary hospitals? And let it be remembered there are no sinecures on the voluntary hospitals, all work and work hard in their turn. This alleged understaffing, it is said, leads to overcrowding of the out-patient departments, and is even asserted to be responsible for the long waiting lists for admission to beds. So far from this being so, the contrary is the truth—that the staff are so numerous that there is scarcely room enough for them to do their work; the popularity of these voluntary hospitals is becoming their undoing; for the demands made on them are far beyond all that was contemplated at their

The paragraph on "Nurses" opens with the very true remark that they are grossly underpaid. But it fails to mention the strenuous efforts made in recent years, with a large measure of success, to better their pay, to improve their housing accommodation, and to ensure them pensions, though much remains to be done in this last respect. The Labour party does not contain the only friends of the nurses. Under "Patients" it is alleged that they are unhappy in these hospitals, "for the nurses pay no regard to the mentality of the individual patient, and a general brisk cheerfulness takes the place of any real sympathy or understanding. All medical instructions are faithfully followed, but any needs or demands of the patients outside of these tend to be ignored, and a cut-and-dried unintelligent course of procedure results, against which a private patient would revolt at once." What would the shade of Florence Nightingale say to this reflection on the devotion of her disciples? Not less inaccurate is the statement: "Another cause of lack of confidence and a certain reluctance on the part of patients to enter a hospital is a widespread feeling that they may be made the subjects of experimental treatment." If this be correct, why those long waiting lists? Since it is false, the mere tittle-tattle of cranks, why give publicity to a statement that will increase the alleged fear to the detriment of the sufferers?

On the "Choice of Patients" there is criticism of "letters of recommendation." That the system is very liable to abuse will not be denied, and for many years past the Association has taken action to remedy any proved abuse. Comment is also made on the habit among large business firms of subscribing handsome sums with the expectation of treatment for their employees. But there are also statements which imply a grave kind of abuse on the part of hospital staffs. It is averred that when private practitioners known to members of the staffs send patients to hospitals, the consultant gives preferential treatment to them; and again, that patients are sent to receive private consultations with the members of the staffs at their homes in the expectation that the payment of the fee therefor will advance the patient's chances of admission to hospital. These are allegations which should have been substantiated or not made. If true to any material extent they indicate a scandalous abuse; but we do not believe they are true, or that members of hospital staffs have so low a standard of honour in the consideration of the claims of patients for hospital treatment.

The following concentrated libel upon the administration, the doctors, and the nurses may be quoted: "The system of 'patients' payments' for treatment in the general wards and out-patients' departments of the hospitals is also open to objection. There is a natural bias on the part of the management to admit those who can pay in preference to those who cannot, and, if the fee varies with the patient's means, to select those who pay most. . . . It is difficult for the administration and the nursing staff not to show some slight difference in favour of 'pay patients.'" And lastly, the chances of filling the hospital's coffers leads to the crowding of patients, so that "the quantity of the doctor's work becomes more important than the quality." Such statements are manifestly absurd, for the medical and nursing staffs rarely know on what terms individual patients are admitted; and the doctor does not lend himself to such exploitation, he has too much respect for his work.

According to the Labour party's programme, the remedy for all these alleged abuses is that "hospitals should certainly be free and open to all in need of such services as their general and special departments can and should provide. All things considered, Labour welcomes State and municipal grants towards voluntary hospitals pending the establishment of a complete

publicly supported and controlled hospitals service. It does so for the following reasons: "(1) The hospitals, as hospitals, are necessary for the public welfare, and therefore cannot be allowed to close their doors or their wards for lack of funds. (2) Public grants are the thin end of the wedge, leading to a public hospitals service. (3) As the State and municipal contributions increase, voluntary subscriptions are sure to grow less. (4) The less the voluntary subscriptions the more completely will the hospitals pass under the financial control of public authorities. With complete financial control the management must also pass into the hands of public authorities, till at last all hospitals will be owned, controlled and managed by the public bodies." This is at least a frank statement of an admissions policy, but "in vain is the net spread in the sight of the bird."

Under more general considerations appears the statement that "Undoubtedly in the past the voluntary hospitals have been of the greatest benefit to suffering humanity. . . . Of old, the benefits of hospital treatment were willingly offered and willingly received, and no harm was done; but in more recent times a different spirit has crept in, with the result that Sir Charles Loch, of the Charity Organization Society, once said he was forced to look upon the voluntary hospitals as the greatest pauperizing agency in the country." Yet in the same breath the writers of this document object to the payments by patients for their maintenance and treatment, either when they are ill in hospital or beforehand by means of contributory schemes; they would give it free through the rates; that appears to them to be a harmless and indeed beneficial process. They are insistent that the voluntary hospitals must be swallowed up in State hospitals at all costs, for they are afraid that these charities may live to be a thorn in the side of the unified State scheme that they envisage. "If the voluntary hospitals continue the system of patients' payments, and the public hospitals are free and open to all, which it is essential they should be, there will be a tendency for the former to drift into pay hospitals for the middle classes and the latter to be used by the necessitous poor only. There will then arise a service for the rich and a service for the poor, which is bad from every point of view, and will entail all the evils and odium of the present Poor Law institutions." Should the programme of the Labour party, as indicated in this document, be realized, the prognostications of the writers may prove only too true. As it has been in education so it will be in hospitals; for nothing will prevent the independent minded seeking their own means of treatment or of education. And it may come to pass that in this instance the "establishment" will be held in less esteem than the "free institutions."

The means for the support for all these schemes is to be obtained through the rates, with the sole exception of the great teaching hospitals, which are to be chargeable to the national exchequer. It is said, "In all these ways a complete and efficiently organized public hospitals service can be gradually built up. It can be done so gradually that the cost will hardly be felt." Probably by that time a state of anaesthesia will have come over the helpless ratepayer, or there will be no more of them left to feel. But what of the hospitals? We fear that their final state is aptly described in a phrase of this document: "Many hospitals exhausted by financial difficulties would most likely be only too pleased to give up the struggle and find rest under the public authority." That may prove only too true, for they may find rest in that stagnation which too often marks public control. No doubt the authors of this document mean well, but it is a pity their effort was not submitted to a *Ride's* purge before it was exposed to the light of public criticism.

TEMPORAL LOBE TUMOURS.

It has been said that tumours of the temporal lobe are of all cerebral tumours the most difficult to diagnose, or rather to locate. The disturbances of function consequent on destruction of the cells and fibres of this lobe are productive of few clinical signs. Uncinate seizures, that is the peculiar sensations of taste and smell which Hughlings Jackson described so well, are perhaps the most characteristic localizing signs. These, however, are not very common. Any method of investigation which will allow of a more accurate localization of these tumours will be welcomed by all neurological physicians and surgeons.

In the current number of *Brain* Harvey Cushing, in a masterly paper, calls attention to disturbances of the visual fields in these cases. In thirty-three instances out of a total of thirty-nine in which accurate perimetric charts were made, defects were discovered in the visual fields. The optic radiation as it courses backwards from the geniculate body sweeps round the outer side of the temporal horn of the lateral ventricle. The most ventral fibres in this geniculocalcarine pathway take a wide excursion round the anterior pole of this horn of the ventricle. Adolf Meyer was amongst the first to demonstrate this, and in America the outward sweep of the fibres has been called "Meyer's loop." It will readily be recognized that any lesion invading the temporal lobe will not have to advance very far upon its course before it will involve this portion of the tract. Three drawings by Max Broedel illustrating the course of the fibres are printed in the paper; Cushing calls them "superb diagrams," but the reproductions are not altogether satisfactory.

The material on which Cushing's paper is based has been noted above, but it is worthy of remark that these cases form a part of his huge series of 663 verified intracranial tumours. Of this number 276 involved the cerebrum proper and 59 the temporal lobe. In 20 of these latter cases perimetry was impossible or the results untrustworthy, usually because of lack of sufficient co-operation on the part of the patient. In 25 cases the hemianopsia was incomplete, more or less quadrantic in character. In 8 other cases there was an homonymous hemianopsia; four times the macula was involved. A detailed account of 10 cases is given and will well repay study. The profusion of perimetric charts is of the greatest assistance to the reader, and Dr. Walker, who made them, is to be congratulated upon the results of the labour which he has expended upon them. He has used test objects of varying size, from 10.0 or more to 0.5 mm. diameter. It is interesting to note, as in Cases 5 and 9, that quadrantic defects only became obvious with the smaller test objects. Most of the cases showed diminution in the size of the scotoma after successful operation. Sometimes a complete homonymous hemianopsia shrank to a small quadrantic defect, whilst in cases in which the growth progressed unchecked its extension can be followed by an increasing defect in the fields.

In a general discussion on the symptomatology of temporal tumours Cushing states that only in 14 out of the total of 59 were typical gustatory or olfactory fits found. He calls attention, further, to visual hallucinations as characteristic of tumours in this situation, associated often with uncinate seizures. These hallucinations present actual pictures to the eye of the patient, usually in the blind field, and are often more or less of constant type for the same individual. They tend to be bizarre. Thus one saw "a little black woman engaged in cooking," another a black cat walking across the room, a third people doing strange things, such as

1. "The field defects produced by temporal lobe lesions," by Harvey Cushing. *Brain*, vol. xlv, Part IV, p. 341.

a woman riding a horse with a sheet of music propped before her. No very definite auditory upset was discovered in these patients with tumours of the temporal lobe, although Heschl's gyrus must have been affected in some.

A contribution of this kind forces upon one the importance to the progress of science and to humanity of the grouping of cases in the hands of one man. No good can come from the dissipation of material which is so precious.

SCIENTIFIC SECTIONS AT THE GLASGOW ANNUAL MEETING.

The officers of the Section of Medicine at the forthcoming Annual Meeting of the British Medical Association at Glasgow have chosen the following subjects for discussion. First day: "The prognosis and treatment of chronic renal disease," opened by Professor Hugh Maclean. Second day: "Exophthalmic goitre," opened by Professor George R. Murray. Third day: "Degenerative diseases of the liver," opened by Sir Humphry D. Rolleston. In the Section of Ophthalmology it has been arranged on the first day to discuss the etiology of optic atrophy; the opening addresses will be given by Dr. C. O. Hawthorne, Mr. J. Hogarth Pringle, and Mr. H. Moss Traquair. On the second day a discussion on the clinical significance and treatment of heterophoria will be opened by Mr. A. S. Percival. The third day will be given up to witnessing clinical demonstrations at the Glasgow Eye Infirmary. The officers of the Section of Surgery have found that "The treatment of tuberculous glands," which had been arranged as the subject for discussion on the second day of the Section, had also been chosen by the Section of Diseases of Children. As the latter Section has already invited a number of speakers to introduce and take part in the discussion the Section of Surgery has resolved to withdraw the subject from its own discussions. The secretaries of the Section of Medicine will be glad to have the names of those who wish to take part in the discussions. The names of the officers of the Scientific Sections were printed in the SUPPLEMENT of February 18th, at p. 39. The Sections will meet on Wednesday, Thursday, and Friday, July 26th, 27th, and 28th.

PREVENTIVE MEDICINE IN SOVIET RUSSIA.

We have received a pamphlet (in German) by Dr. Serge Bagotzky on the fight against tuberculosis in Soviet Russia. It is published by the Russian Red Cross in Switzerland, and though no doubt tendentious it contains interesting matter. We are told that before the revolution antituberculosis measures were few and chiefly the product of voluntary organizations, and that even as recently as 1913 only twenty-three sanatoriums with 319 beds existed in Russia. After the Bolshevik revolution all public health services were co-ordinated in a special Ministry section which deals with the problems of tuberculosis. Its organization embraces (1) control of all social measures dealing with tuberculosis; (2) the drafting of orders emanating from the central authority; (3) co-ordination of institutions concerned with tuberculosis; (4) erection of special institutions of both practical and scientific character; (5) propaganda. This is kept in touch with all strata of the population by a commission which appears to resemble what we should call a consultative council, upon which are medical and scientific members as well as representatives of workmen, teachers, and others. The State campaign is directed to improve the conditions of children and pregnant women and the general hygiene of the working classes. In the first place, efforts have been made to secure the feeding of children. A model central children's institute has been established in Moscow, and, it is said, the number of crèches, milk kitchens, and consultative stations has been largely increased. It is stated that 140,000 infants and 14,000 mothers were provided for by February, 1921. Various stringent laws protecting pregnant women have been

enacted. Some of these have a certain grim picturesqueness. For instance, wives of workmen or of soldiers in the Red Army receive 0.7 metre of calico when a baby is born. From the eighth month of pregnancy a woman receives, in addition to the workman's ration, 15 lb. of bread, 1 lb. of butter, and 1 lb. of sugar monthly. Pregnant women need not line up in the queue for ration cards. Other measures do not differ from those familiar to us. Dr. Bagotzky summarizes the guiding principles of the campaign under the following five headings: (1) Complete State control (*Verstaatlichung*) of antituberculosis measures as of the whole field of medicine (*Medizinalwesen*); (2) assumption by the State of responsibility for child welfare; (3) assumption by the State of responsibility for the care of the sick and infirm, especially in the proletariat population; (4) centralization of all antituberculosis campaigning; (5) measures to obtain the active co-operation of all strata of the population, especially of the working classes, in organized antituberculosis measures. Perhaps the first reflection of an English reader of newspapers will be that there is some difference between what is enacted and what is effected even west of Soviet Russia, and he may recall Burke's apophthegm: "Let us be saved from too much wisdom of our own, and we shall do tolerably well." But the name of Burke should warn us that even a man of great genius and learning may form a very incomplete judgement of the nature and consequences of a social revolution, and should increase our regret that the materials for estimating the effects of such experiments in preventive medicine as those summarized in Dr. Bagotzky's pamphlet are so scanty and so adulterated with prejudice. It is probably correct to say that the Englishman of 1922 has no better means of learning the truth about Soviet Russia than had his ancestor of deciding between Burke and Paine.

ALCOHOL IN RELATION TO INDUSTRY.

In an address on alcohol in relation to industrial hygiene and efficiency, which Sir Thomas Oliver gave before the Royal Society of Arts on March 29th, he said that customs died hard, and yet, on the whole, it might be said that there was less heavy drinking among all classes to-day than there was a few decades ago. Factory work was run on a higher plane, and to-day the artisan began his day's work after having breakfasted at home and without being tempted to purchase stimulants on his way to the factory. Any inquiry into the relation of alcohol and industrial hygiene must have regard to the home conditions of the worker and the manner in which he spent his leisure hours. What merited consideration was rather the effect of the moderate use of alcohol during their leisure hours upon the producing capacity of working men than the premature development of disease and its disabling consequences. Professor Edward Mellanby had made a careful experimental investigation of the conditions which affect the absorption of alcohol, and he found that usually, but not always, the effects produced upon the nervous system were proportionate to the amount of alcohol circulating in the blood. The blood got rid of the alcohol by a process of oxidation, and it was while this was being accomplished that a certain amount of energy was liberated within the body which was utilizable. The larger the amount of alcohol present in the liquid consumed the more quickly was the maximum of alcoholic concentration in the blood reached and symptoms of intoxication produced. Yet there were certain idiosyncrasies—for instance, whisky was found to be more rapidly absorbed than stout even when the percentage of alcohol was the same in the liquid imbibed. It was Sir Lauder Brunton's opinion that alcohol in moderate doses increased the pulse rate, while the opposite view was expressed by Sir Victor Horsley and Sturge. In a sense all of them were right, for alcohol increased or depressed the pulse rate according to the circumstances prevailing at the time. Dodge and Benedict had found that after the ingestion of alcohol there was in almost every instance a relative acceleration of the pulse, meaning by relative acceleration a more rapid pulse than occurred at

corresponding hour of normal days. They maintained that the increased pulse rate occurred in practically all persons as an effect of alcohol during mental and physical activities, and they inclined to the view that the chief effect was produced on the centres regulating simple muscular movements, rather than on the intellectual centres. Alcohol was certainly not assimilated and did not enter into the composition of the tissues, and on these terms could not be regarded as a food. If, however, it was capable in the body of supplying energy when it was a food, but of an indirect kind, for when alcohol had been absorbed only about 5 per cent. of it was eliminated from the body as such, the remaining 95 per cent. being retained in the body to undergo combustion and be used. It was generally admitted that the subdivision of labour and the multiplication of machinery had made present-day work monotonous, and in certain quarters there was a feeling that alcohol by paralysing the critical faculty dulled the senses to the influence of monotony. Sir Thomas Oliver, while admitting that monotonous work might be a cause of drinking, contended that the remedy was not to denounce alcohol solely but to widen the interests of the working classes by making work more congenial. So far as the man who used alcohol sparingly and in moderation was concerned, neither experience nor physiology showed that he was as a workman inferior to the abstainer. An experiment on a gigantic scale was being carried out by the United States, and the civilized world awaited with patience its results, for by many persons it was held that those nations have been the most progressive whose people had been protein consumers, largely of meat, and who had not denied themselves the luxury of alcohol. It could not be said of the Mohammedan races of Asia and of Eastern Europe, for example, that total abstinence had raised them to a higher plane of civilization or had conferred upon them those practical qualities so characteristic of the men of the West.

AUTO-SUGGESTION AND THE CONÉ METHOD.

M. Coné's present visit to this country is attracting more attention than any of those he has previously paid us. The way has been well prepared for him, partly by reverent enthusiasts and partly by irreverent persons who have succeeded in making his name known even to music-hall audiences. M. Coné, who is not, we believe, a member of the medical profession, holds a clinic in his house and garden at Nancy, and to some extent he is in the line of descent of the Nancy school of hypnotism; he diverges from it partly by not directly seeking to produce the hypnotic state, and partly by placing great reliance on what is called auto-suggestion. He does not refrain from resort to suggestion; on the contrary, he makes use of it freely, his favourite phrase in beginning to treat pain or disability being "ça passe," which he makes his patients repeat after him "so fast as to produce a sound like the whirring of a rapidly revolving machine." But he relies more upon inducing patients to think that they are better, or are getting better, or are going to get better. This state of mind he seeks to bring about by inducing the patient to repeat the formula, which is in French "Tous les jours, à tous points de vue, je vais de mieux en mieux." The English version M. Coné considers the most satisfactory is "Day by day, in every way, I'm getting better and better." In this way he seeks to influence the unconscious mind, his basic law being "Every idea which enters the conscious mind, if it is accepted by the unconscious, is transformed by it into a reality, and forms henceforth a permanent element in our life." The formula "day by day," etc., or "ça passe," which is to be translated "it's going," must be repeated very rapidly, so that the contrary suggestion that the pain is not going, or the asthma is not diminishing, or bad temper is not disappearing, will not intrude itself. You repeat the phrase "It's going" very rapidly until you feel justified in concluding the series by exclaiming "going, going, gone!" All this sounds a little childish, but it at least fulfils the therapeutic maxim, *primum non nocere*. M. Coné will even use the method in cases of organic disease in an advanced stage,

not rejecting the possibility of cure, but admitting its unlikelihood. Here, indeed, seems to lie the risk of the method, since persons with organic disease susceptible of cure by operation or otherwise may go on assuring their "unconscious" that "it's going" or "I'm getting better," until the condition becomes incurable. We are informed that M. Coné does not accept fees for his services, but that a pamphlet by him, entitled *Self-Mastery*, is for sale.¹

THE SANITARY OFFICERS ORDER, 1922.

THE coming into force on April 1st of the Public Health (Officers) Act, 1921, has necessitated the issuing by the Minister of Health of a new Order with respect to the conditions of appointment and duties of medical officers of health and sanitary inspectors. Opportunity has been taken to revoke no less than five previous Orders. The new Order applies either wholly or in part to nearly all medical officers of health and sanitary inspectors. Part-time medical officers of health appointed or reappointed after April 1st last must be appointed for a specified term ending on the following March 31st, and will continue to hold office from year to year unless three months' notice, expiring on any March 31st, is given to terminate the appointment. A similar regulation applies to a whole-time sanitary inspector who is not a senior inspector and one-half of whose salary is payable by a county council or county borough council. A part-time medical officer of health may at any time, with the consent of the Minister of Health, be appointed by a local authority as a whole-time officer, in which case he obtains security of tenure under the Public Health (Officers) Act, 1921. The appointment of a medical officer of health as well as of a sanitary inspector is subject to the approval of the Minister, and every appointment before being made must be advertised. The new regulations with regard to the qualifications of those officials one-half of whose salary is paid out of Exchequer grants are of great importance. A medical officer of health must hold a diploma in sanitary science, public health, or State medicine, or he must have had not less than three years' previous experience of the duties of a medical officer of health. A sanitary inspector must hold the certificate of the Royal Sanitary Institute or of the Sanitary Inspectors' Examination Board. The Minister of Health may, however, dispense with this requirement, or indeed with any of the requirements of the Order, in any case in which it seems desirable to him to do so, provided he is satisfied that the interests of any person will not be prejudiced thereby. The salary paid to the medical officer and to the inspector must be approved by the Minister. The duties to be performed by the medical officer of health are set out much more concisely than in previous Orders, as a memorandum dealing more fully with the subject is in course of preparation. The seventeen paragraphs relating to the duties of a sanitary inspector in the 1910 Order have been reduced to twelve. The important additional duty is cast upon an inspector of supervising the scavenging of his district if so directed by the local authority. He may also be required to act as officer of the local authority under the Rats and Mice (Destruction) Act, 1919. A great deal of care has been bestowed on the drafting of the new Order, and it ought to meet with the approval of all those who desire to increase the usefulness of the public health service. Further particulars are given this week in the SUPPLEMENT.

MEAT INSPECTION.

ALTHOUGH the efficient inspection of meat supplies has long been recognized to be one of the most important duties of sanitary authorities, these bodies appear to have very different ideas as to the manner in which their obligations in this

¹ The quotations are from a small book, *The Practice of Auto-suggestion by the Method of Emile Coné*, by C. H. Brooks; for it M. Coné has written a foreword, in which he says that Mr. Brooks has skillfully seized on the essentials and put them forward in a simple and clear manner. The method is one which M. Coné says "everyone should follow—the sick to obtain healing, the healthy to prevent the coming of disease in the future." (London: George Allen and Unwin, 1922. 121 pp. Price 3s. 6d. net.)

respect should be discharged. In some localities the inspection is carried out by well-trained officials, and is thorough and complete; in others there is, for all practical purposes, no inspection at all; between these two extremes are a very large number of districts in which inspections are made by sanitary inspectors who have had no special training in the duties of meat inspection. At the end of 1921 a Departmental Committee reported to the Minister of Health as to the administrative measures necessary to secure adequate protection for the health of the people in connexion with the slaughter of animals and distribution of meat for human consumption. Some of the recommendations of the Committee can be carried out without recourse to further legislation, while others will require the sanction of Parliament; in the latter category is a proposal that there should be a system of marking of meat which has been duly inspected at the place of slaughter. Without waiting for increased statutory powers a great deal can be done by local authorities by way of increasing the efficiency of inspection. To this end the Minister of Health has issued a memorandum in which he sets out the system of inspection he recommends for adoption. The routine of this inspection is the minimum which would be followed by a well-trained inspector, and the details are sufficiently clearly expressed to enable a partially trained inspector to make a much more thorough inspection than he has perhaps been in the habit of doing. It is recommended that the entire carcass and organs shall be condemned when there is found either generalized tuberculosis or tuberculosis with emaciation, and a very clear statement is made as to the conditions which should assist in determining whether the disease is generalized. Where there are only localized lesions it is recommended that the parts containing the lesions and the contiguous parts shall be condemned. A list of thirty-three conditions is given, the existence of which should lead to the condemnation of the entire carcass. This official recommendation should serve to bring about greater uniformity in the action of meat inspectors than has hitherto prevailed. In a circular accompanying the memorandum the Minister of Health refers with approval to the recommendation of the departmental committee that local authorities in charge of markets or large abattoirs should be urged to give facilities for demonstrations which inspectors and candidates for meat inspection certificates might attend. He concurs also in the suggestion of the committee that there should be two grades of inspectors: one of "lay inspectors,"—that is to say, sanitary inspectors holding a meat certificate, possessing sufficient knowledge of the work to enable them to recognize abnormalities, to decide and interpret a definite schedule of inspection, and to recognize those cases requiring more expert knowledge than they possess; the second grade would include expert inspectors, presumably qualified veterinary practitioners, who could assist the lay inspectors in time of difficulty, and in large areas would supervise their work.

CONGRESS OF RADIOLOGY AND PHYSIOTHERAPY.

A congress of radiology and physiotherapy was to have been held in London in April, 1921, and it was expected that many representatives of France and Belgium would take part in the proceedings. Owing to the threat at that time of a railway strike the congress was postponed. It will be held this year from June 7th to 10th. Like the congress which was to have taken place last year, it has been arranged by the Section of Electro-therapeutics of the Royal Society of Medicine and the British Association for the Advancement of Radiology and Physiotherapy. The president is Sir Humphry Rolleston, K.C.B., and the arrangements are being made by an executive committee, of which Sir Archibald Reid, K.B.E., is chairman, and Dr. Lynham secretary. There will be three sections—radiology, physiotherapy, and electrology. In the first-named section, of which Dr. C. Thurstan Holland of Liverpool is president, the first day (Wednesday, June 7th) will be given to a consideration of the stomach, the conditions of the normal stomach being discussed in the morning, and of the abnormal stomach in the after-

noon. The morning discussion will be opened by Dr. Barclay of Manchester, Dr. Peremans of Antwerp, and Drs. Colombin and Tribont of Paris. The afternoon discussion will be opened by Dr. Bécélère of Paris, Dr. Murdoch of Brussels, and Sir Archibald Reid. The other subject to be discussed by this section—namely, deep therapy by x rays and radium—will occupy the whole of Thursday and the morning of Friday, June 9th. The opening papers will be contributed by Dr. Ledoux-Lebard and Madame Laborde of Paris, Dr. Casman of Antwerp, Mr. Hayward-Pinch, F.R.C.S., Director of the London Radium Institute, and Dr. Robert Knox. In the afternoon of June 9th demonstrations will be given at various hospitals, including one on intraperitoneal injection of oxygen at St. Bartholomew's Hospital. The Section of Electrology, which meets under the presidency of Dr. E. P. Cumberbatch, will give the morning of June 7th to the discussion of the action of the direct current (constant) on the tissues beneath the skin and mucous membrane; it will be introduced by Dr. Turrell of Oxford. On June 8th a discussion on the uses of electrical methods in the diagnosis and prognosis of paralysis will be opened by Dr. R. Woods of London and Dr. Bourguignon of Paris. On Friday, June 9th, Dr. Cumberbatch of London and Dr. Nobels of Ghent will introduce the subject of the physiological action and therapeutic uses of high-frequency currents. The first subject to be debated by the Section of Physiotherapy, which meets under the presidency of Dr. J. B. Menzell, will be cardiac disorders, introduced by Professor Bergonié of Bordeaux and Drs. Justina Wilson, Parsons Smith, and Hunt of London. On June 8th the re-education of muscles and the treatment of scoliosis will be discussed, and on Friday, June 9th, backache and referred pain. Applications for membership of the Congress should be addressed to the honorary treasurer, Dr. James Metcalfe, 123, Harley Street, and should be accompanied by the amount of the subscription if not already paid—namely, two guineas to British members and 40 francs to French and Belgian members. Communications with regard to discussions should be addressed to the honorary secretary of the section concerned—namely, radiology, Dr. N. S. Finzi, 107, Harley Street, W.; electrology, Dr. Murray Leveick, 36, Harley Street, W.; and physiotherapy, Dr. P. Jenner Verrall, 1A, Portland Place, W.1, or Dr. L. D. Bailey, 42, Eaton Terrace, S.W.1. An exhibition of x-ray and electrical apparatus is being arranged by a committee, of which Dr. Ulysses Williams, 128, Harley Street, W., is honorary secretary.

THE LEUCOCYTIC COUNT IN INFANTS.

That considerable variations can occur in the numbers of leucocytes under definite physiological conditions in adults is appreciated by all haematologists, but the limits of such variation are fairly well agreed upon. It is otherwise in infants, especially nursing infants. In one and the same infant, even during a short space of time, relatively enormous differences can be found, so that any single figure given by an author as a typical normal count cannot be accepted. The possible fallacies of blood counts are not so generally recognized as they should be. The number of leucocytes in a first drop of blood may differ very widely from the numbers in succeeding drops; successive counts from the same drop, even in well-shaken pipettes, show such variations that the average of several must be taken; the smaller blood-counting chambers, such as the Thoma-Zeiss, give results far from accurate. These are only a few of the possible sources of fallacy, and when it comes to a differential count on slides—a slovenly practice too often adopted—the errors may be so magnified that many observers have doubted the utility of leucocytic counts unless the changes are very marked. But even with the most scrupulous technique, few will be inclined to draw conclusions from an enumeration of the white corpuscles in children. Numerous factors exercise an influence on the leucocytic equilibrium. Of these the influence of digestion would seem to be the most important. It has also been shown that the position of the patient, erect or recumbent, has an effect on the numbers. The vasomotor reflexes

deal applications of heat or cold, the electric stimulation of nerves, pain, emotional states, and surrounding temperature evoke quite evident leucocytic variations. The influence of rying is specially held responsible for changes in children. All this goes to show that the leucocytic titre is essentially unstable and that according to the time and to the circumstances considerable differences may be encountered. Abel and Brenas¹ have sought to ascertain the variations in infants apart from the factors of digestion. They took samples of blood from children who had had no milk for over six hours, merely a drink of sugared water which, it had been previously ascertained, did not affect the leucocytic curve. Enumerations were made every twenty minutes for three hours. This was repeated after some days' interval. It was found that each individual showed a characteristic curve: some, a low average of leucocytes with small undulations, others a high average with larger and more sudden scillations. In all cases the line was never horizontal. Between the maxima and minima mean differences of two or three thousand leucocytes were found; indeed, in some cases differences of over five and six thousand were obtained. The authors state that in the majority of their cases they could not attribute these variations to any particular factors.

PATHOLOGICAL AND BACTERIOLOGICAL LABORATORY ASSISTANTS' ASSOCIATION.

Under its new constitution the Association of Assistants in Pathological and Bacteriological Laboratories is now admitting as associate members laboratory assistants from laboratories other than those of pathology and bacteriology. The organization, which is not a trade union, was founded in 1912, its chief object being to improve the status of the laboratory assistant by endeavouring to raise the standard of technical knowledge through the medium of an educational programme, culminating in an examination and the granting of a certificate of proficiency in laboratory technique. The examinations are conducted by an examining council in co-operation with the Pathological Society of Great Britain and Ireland. To encourage the systematic teaching of the junior members, lectures and classes in the technique of pathology and bacteriology are conducted by members of the medical profession and of the Association throughout the winter session. An official organ, the *Laboratory Journal*, is issued to members quarterly; in addition to Association news it contains original articles and abstracts of technical interest to laboratory workers. There is also an employment bureau, as to which Mr. F. Norman, Now Haw, Weybridge, will give information. From the first the founders had in mind the inclusion ultimately of all laboratory assistants in one federation, and the object of the present movement is to further the realization of that ambition. It is hoped that as willing workers forthcoming there will spring from the associated membership sections embracing other branches of science following along the lines of the educational programme laid down by the parent organization. In the formation of the associated sections the parent association is prepared to afford assistance financially and by such other means as lie in its power. The Honorary Associate Secretary is Mr. F. C. Colley, 2, Eldon Place, Reading, to whom all applications for associate membership should be made; he will be pleased to furnish any further information.

POST-GRADUATE COURSES IN LONDON.

The Fellowship of Medicine and Post-Graduate Medical Association has arranged a short course in general medicine in which members of the staff of various hospitals have been invited to take part; it will begin on Monday, May 1st, and end on Saturday, May 13th. The course will include clinical lectures and demonstrations in pulmonary affections, disease of the heart, dermatology, mental disorders, children's diseases, and pathology, covering a full day's programme for the two weeks. Another course of six lecture demonstrations on gastro-intestinal affections in children will be given at the

Children's Clinic, Western General Dispensary, on Mondays and Thursdays, from May 15th to June 1st, at 5 p.m. Copies of the syllabus and other particulars regarding fees, etc., of both of these courses and of the *Bulletin* will be forwarded on application to the Secretary of the Fellowship of Medicine, 1, Wimpole Street, W.1. By the kindness of the Royal Society of Medicine the Fellowship is arranging to resume the lectures which were so successful in the earlier days, and during May, June, and July it is hoped to hold a lecture in the Society's House once a week at 5 p.m. Sir Arbuthnot Lane, Bt., Sir Humphry Rolleston, K.C.B., and others, have promised to contribute, and the full programme will be announced shortly. These lectures will be open to the profession generally. A post-graduate course, which fulfils the requirements of the regulations for the Diploma of Psychological Medicine in regard to instruction in nervous diseases, will be held at the National Hospital for the Paralysed and Epileptic, Queen Square, Bloomsbury, W.C.1, from May 15th to June 30th. Dr. J. G. Greenfield will deliver lectures on the pathology of the nervous system; Dr. Gordon Holmes, Dr. Hinds Howell, and Dr. Kinnier Wilson will lecture on the anatomy and physiology of the nervous system; Dr. W. J. Adie will demonstrate methods of examination of the nervous system; out-patient clinics will be held at the Hospital on the afternoons of Mondays, Tuesdays, Thursdays, and Fridays; and clinical lectures and demonstrations will be held on Wednesday afternoons. An inclusive fee of ten guineas will be charged for the whole course, but any part of the course may be taken separately at a special fee. A special arrangement can be made for those unable to attend the whole course, and for details applications should be made to the dean of the medical school. Fees should be paid to the secretary of the Hospital on entering for the course.

THE CINEMATOGRAPH AND VIVISECTION.

The suggestion by Dr. Chalmers Mitchell that cinematography might to some extent replace animal experiments in the teaching of physiology has been seized upon by Mr. Stephen Coleridge and other antivivisection agitators to make an attack on experimental medicine. Other correspondents who wrote to the *Times* showed a complete ignorance of the nature of class demonstrations in physiology. The situation is clear enough and is admirably stated by Professor Starling in the letter which we reproduce at page 570. The law regarding class demonstrations is extremely plain and simple: the animal operated on must be fully under an anaesthetic during the whole experiment and must be killed before it recovers consciousness. That law is of course rigidly and scrupulously obeyed, and it is obvious that no experiment causing any pain whatever to an animal can be performed as a class demonstration. The correspondence that has occurred in the *Times* is a striking tribute to the skill with which the various antivivisection societies have disseminated falsehood and prejudice concerning animal experiments. It is very remarkable that so many fairly well informed persons should have been so misinformed as to the laws and regulations under which experiments upon living animals are performed. The exact value of the cinematograph as a means of instruction is a highly interesting question; it seems to hold out considerable possibilities in the teaching of many branches of medical and allied sciences, and has already been used a good deal for this purpose since the time of Marey, who was one of the first to photograph movement. Humanitarian questions are not, however, involved in this matter.

We regret to announce the death of Dr. Francis D. Boyd, C.B., C.M.G., Moncrieff Arnott Professor of Clinical Medicine in the University of Edinburgh and physician to the Royal Infirmary. We hope to publish a biographical notice in a subsequent issue.

We understand that Lieut.-General Sir John Goodwin's period of office as Director-General Army Medical Services, which terminates on June 1st, 1922, has been extended for a year.

Medical Notes in Parliament.

[FROM OUR PARLIAMENTARY CORRESPONDENT.]

National Insurance Bill.

THE bill introduced on March 29th by Sir Alfred Mond "to make further provision with respect to the cost of medical benefit and the expenses of the administration of National Insurance benefits" has been printed. Though the proposals are different from the recommendations of the Geddes Committee for the abolition of the Exchequer Grant for medical services, they had their origin in the Committee's report. As from January 1st, 1920, the capitation fee to insurance medical practitioners was increased to 11s. a year. This rate of payment was on January 1st, 1922, reduced to 9s. 6d., and it has been reckoned to leave a balance of about 2s. 6d. per insured person to be paid by the Treasury to the Insurance Committee. To free the Exchequer from this cost the Geddes Committee advised that the contribution from employers and employed should in each case be raised one halfpenny a week per insured person. It was stated that the actual amount of extra contribution required to balance the account would not be much more than a halfpenny a week, but it would have been difficult to apportion as between employer and employed; and so the suggestion was put forward by the Geddes Committee that there should be an equal extra charge of one halfpenny a week and some benefits added. Conference with the representatives of the approved societies, however, showed that they were willing to undertake the extra liability on terms which are embodied in this bill.

The first section of Clause I lays down that there shall be paid each year out of the Benefit Fund of every Approved Society: (a) to Insurance Committees in England on account of the cost and expenses of the administration of medical benefit a sum not exceeding 2s. 4d. a year for each insured person under Section VII of the Act of 1920; and (b) to the Minister of Health on account of the expenses of administration incurred by him a sum not exceeding 1d. per week in respect of each of the total number of the members of the Society.

Section 2 provides that

"There shall be credited to each society out of moneys provided by Parliament in such manner and at such times as may be prescribed by regulations to be made by the National Health Insurance Joint Committee with the approval of the Treasury, such sum (to be calculated in such manner as the regulations may prescribe) as would by virtue of section three of the National Insurance Act, 1911, be payable out of moneys provided by Parliament if the sums paid by the society under this section, together with interest thereon from the date of payment at the rate prescribed for the purposes of paragraph (c) of subsection (1) of the section fifty-six of the National Insurance Act, 1911, were, on the valuation of the society made next after the passing of this Act, applied for the purpose of additional benefits under the National Insurance Act, 1911."

This section is to come into operation as from April 1st of the present year, and subsection 1 of this section is to continue in force until December 31st, 1923.

Clause II of the bill would abolish the Women's Equalization Fund which was established under Section 2 of the Act of 1918, and this is deemed to have had effect as from January 1st of the present year. The section is to apply to Northern Ireland.

Clause III provides for the application of part of the sums unclaimed in stamps sales account towards cancellation of arrears of payment by insured persons. Hitherto the Central Fund has had the advantage of this uncalculated and uncertain profit. Under this clause the National Insurance Joint Committee is to be empowered to transfer sums to approved societies to be applied to prevent members who are in arrears from being or continuing to be suspended from benefit. The section is to continue in force until December 31st, 1922.

Clause IV sets forth that in the application of the Act to Scotland 2s. 9d. shall be substituted for 2s. 4d. and 2d. for 1d. In the application of the Act to Wales the sum of 2s. 11d. is to be substituted for 2s. 4d., and the sum of 2d. is to be substituted for 1d.

Ministry of Health, Insurance Department.—Dr. Farquharson asked the Minister of Health, on March 29th, by what method the salaries, wages, and allowances of the administrative staff, the general clerical staff, and the Insurance Department staff were appropriated for payment by the Exchequer or National Health Insurance Fund respectively. He inquired why only £130,600 could be recovered from the National Health Insurance Fund, seeing that the cost of the Insurance Department staff of the Ministry amounted to £159,267, and that of the general clerical staff to £329,650—a total of £188,917. He also invited the Minister to explain why the increase for 1922-23 of the amount recoverable from national health insurance funds amounted only to £22,945, having regard to the fact that the increased cost of the general medical staff and insurance department for the same year amounted to £137,612. Sir A. Mond replied that the whole of the salaries of the staff employed in the Insurance Department were paid out of money provided by Parliament, but the cost of the staff employed on the work of detailed administration of benefits carried out by the department was recovered from insurance funds and appropriated in aid of the vote. This work embraced the administration of the Deposit Contributors' Fund, the Navy and

Army Insurance Fund, the Exempt Persons' Fund, and the Approved Societies' Officers' Guarantee Fund. The sum estimated to be recovered in 1922-23—namely, £130,600—was the estimated actual cost of this work for the year. The cost of the medical referee service, in so far as it was concerned with the administration of benefits, would also be recovered from insurance funds; and an appropriation in aid of £50,000 was estimated for on that account. The increase of the amount estimated to be recovered from insurance funds in 1922-23, as compared with 1921-22, was £77,300, and not £22,945 as stated by Dr. Farquharson. The cost of general clerical staff, to which reference had been made, was for the whole work of the Ministry, and not for the Insurance Department only.

The Insurance Card.—Dr. Macnamara, in moving the second reading of the Unemployment Insurance Bill, on March 29th, recalled that a joint committee appointed by the Minister of Health and himself was considering whether it was practicable to have a single card and a single set of stamps for health insurance and unemployment insurance instead of two cards and two sets of stamps as at present. Owing to the complication of the matter immediate action could not be expected. The Committee had reported that it would not be practicable to bring the single card into use next July.

Nurses and Unemployment Insurance.—Mr. Lyle, in the same debate, raised the case of hospital nurses; he said that a hospital which was advised that nurses were not really included under the old Act was taking a case into court. But the Minister had said they were, and most of them had paid their contributions. Nurses objected to being brought into the scheme, partly because there was little unemployment and they were not inclined to go to the exchanges and form up in queues and wait for doles. Nurses engaged in hospitals had no risk of being unemployed, yet they had to pay contributions. Dr. Macnamara said that nurses were not unanimous in the objection. The National Union of Trained Nurses, in a letter to him of November 8th, 1921, said that though they considered the existing arrangements for administering the Insurance Act for nurses totally unsuitable, yet they did not think that the grant of an exemption would be a wise departure. The nurses could administer the scheme themselves, but as that would involve an addition to the benefits from their own funds he recognized difficulty. He promised, however, to consider the question whether the collection of these contributions from the two sides was justified. In Grand Committee on the bill on April 4th an amendment to exclude hospital nurses was carried.

General Nursing Council.—Mr. T. Griffiths asked, on April 3rd, whether Sir Alfred Mond had informed the General Nursing Council that he was prepared to sanction any rule consistent with the Act which the Council thought necessary. Sir A. Mond replied, that he had given no such pledge. He had intimated to the chairman of the Council that he would approve such rules consistent with the Act as the Council thought necessary to meet the serious difficulties which had arisen, and to speed up registration and secure an adequate electorate within the time allowed under the Act.

Salaries of Health Visitors.—Sir Alfred Mond, on April 3rd, informed Mr. Swan he had received representations that the salaries of some health visitors were inadequate. He agreed that these officers discharged duties of great value to the State, but subject to the necessary services being adequately performed he did not think that in present circumstances he ought to require local authorities to pay salaries in excess of what they themselves considered necessary.

Health Services Expenditure.—On March 30th Sir Alfred Mond said that a sum of £1,221,528, mentioned in a question by Dr. Farquharson, represented the estimated net cost in England for 1922-23, not only of the administration of local government services, but also of central insurance administration and certain other services. The corresponding figure in the 1914-15 estimates was £598,267. Included in the amount for 1922-23 was £461,500 for war bonus, an item for which no corresponding provision had to be made in 1914-15. The balance was accounted for by the expansion, made in 1914-15, of the functions of the Ministry of Health, especially in the direction of housing, maternity and child welfare, tuberculosis, venereal diseases, and other services.

Pensions Appeal Statistics.—In reply to Major Keller, on April 3rd, Major Tryon said that since their institution in November, 1919, Medical Appeal Boards had examined approximately 126,000 officers and men. In 55 per cent. of the cases the assessment had not been altered, in 33 per cent. it had been raised, and in 12 per cent. it had been lowered. He wished it to be understood that these figures referred to the Ministry's Medical Appeal Boards, and not to the Pensions Appeal Tribunals. In answer to Mr. Clynes, Mr. Chamberlain said his information was that the present arrangement for Pensions Appeal Tribunals met with the approval of the ex-service men's organizations. But if Mr. Clynes had any substantial complaint or constructive suggestion that he wished to bring forward, the Minister of Pensions would arrange for a conference with him at which the Lord Chancellor would be represented.

Ex-Service Men in Asylums.—Major Barnston, for Sir Alfred Mond, stated on March 30th that the number of ex-service men classified as service patients, in country and borough mental hospitals in England and Wales on January 1st, 1922, was 4,921, as compared with 4,673 on January 1st, 1921. He gave particulars of the asylums in which the men are being treated, which show that they are distributed among 92 asylums situated in all parts of England and Wales.

Chemicals under the Safeguarding of Industries Act.—Dr. Murray died, on April 3rd, whether the President of the Board of Trade is aware that after exhaustive hearings before the referee under art I of the Safeguarding of Industries Act it was admitted by the department, manufacturers, merchants, and scientists that in terms in the schedule "all other fine chemicals" could not be interpreted; and if so, what steps he proposed to take to rectify the matter. Mr. Baldwin said the doubts which had arisen related to only a limited number of cases, which were of a borderline character, and provision for any of these was made in the Act itself.

Asphyxiating Gas.—Mr. Morrison, on March 27th, asked whether in view of the agreement of Washington, under which the use in war of asphyxiating gas was prohibited, it was proposed to close down the experimental ground at Porton. Sir Robert Sanderford answered in the negative. The Government would be failing in its duty if it did not take all possible steps which might be necessary to protect the forces of the Crown and the inhabitants of the country against gas attacks in time of war.

Small-pox in the Philippines.—Sir A. Mound, at the instance of Mr. Waterton, gave the following figures of small-pox cases and deaths in the Philippines:

	Cases.	Deaths.
1915 ...	6,265	216
1916 ...	2,520	554
1917 ...	542	255
1918 ...	47,369	16,447
1919 ...	63,180	41,308
1920 ...	10,448	4,385
1921 ...	1,823	790

The Consumption of Alcoholic Liquors.—Asked, on March 28th, by Mr. Hurd, the average consumption of beer and stout and spirits in 1921, compared with that in 1913, on the basis of alcoholic content, Sir Robert Horne said that he could not give the information in the form desired. The estimated quantities, measured in casks of proof spirit, per head of the population, retailed for consumption in the United Kingdom in the years ended December 31st, 1913, and 1921, were as follows: In 1913, 2.61 gallons of beer and stout, and 0.79 gallon of spirits; in 1921, 1.9 gallons of beer and stout, and 0.39 gallon of spirits.

Grading of Milk.—Viscountess Astor asked, on March 29th, whether the Minister of Health was aware that much milk described as nursery, invalids', guaranteed, etc., was merely milk of ordinary quality. Sir A. Mound said he knew this was the case, but had no power to prohibit the use of such descriptions. He hoped that in time it would be recognized that the only designation on which specific reliance could be placed were those authorized by the official grading scheme. He was aware that much of the milk sold in London and in some provincial towns was treated by a process of so-called "pasteurization," but he did not think that this milk was generally sold as raw milk. He had no power to require pasteurized milk to be sold as such, but the matter was under consideration in connexion with further legislation.

ROYAL MEDICAL BENEVOLENT FUND.

At the meeting of the Committee held on March 14th 32 cases were considered and £453 voted to 28 applicants. The following is a summary of some of the cases considered:

Widow, aged 55, of L.S.A. Lond. who died in 1921, and three children left unprotected. As applicant was a trained nurse prior to her marriage she is anxious to get a house on the South Coast and take children to school. Received £20 from the Masonic Lodge and £10 from the Royal Medical Benevolent Fund. Voted £20 in four instalments.

Widow, aged 50, of L.R.C.P. Dubl. who died in 1919. Applicant has a house at the seaside and lets apartments during the summer months and in the winter she and her daughter take daily work. They realized £11 8s. 6d. last year and the rent and rates came to £35 per annum. The youngest daughter goes to school daily and lives at home. Voted £20 in four instalments.

Daughter, aged 53, of M.R.C.S. Eng. who died in 1907. Applicant is a trained nurse, but owing to ill health the work is too heavy for her; she is now receiving free training to become a health visitor and asks the Fund for a grant towards maintenance during training. Voted £26 in four instalments.

Daughter, aged 29, of L.S.A. Lond. who died in 1894. She received last year £107 from teaching. Her mother is in receipt of a grant from the Fund of £18 in twelve instalments. She wished to start a preparatory school. Voted £25 to the Royal Medical Benevolent Fund Guild, who have promised to supplement this by a similar amount if they consider the scheme satisfactory.

Subscriptions may be sent to the Honorary Treasurer, Sir Charles J. Symonds, K.B.E., C.B., F.R.C.S., at 11, Chandos Street, Cavendish Square, London, W.1. The Royal Medical Benevolent Fund Guild is overwhelmed, in these days of exorbitant prices for clothing and household necessities, with applications for coats and skirts for ladies and girls holding secretarial posts, and suits for working boys. Gifts should be sent to the Secretary of the Guild, 43, Bolsover Street, W.1.

The fourth Italian Congress of Radiology will take place at Bologna, from May 9th to 11th, in the Institut Rizzoli, with Professor Aristide Basi as president. Full particulars may be obtained from the secretary of the Congress, Dr. Alberto Possati, Villa Verde, Bologna.

Scotland.

POST-GRADUATE TEACHING IN GLASGOW.

Under the auspices of the Glasgow Post-Graduate Medical Association arrangements have now been completed for the provision of clinical teaching for medical practitioners throughout the year. Most of the hospitals, general and special, are taking part in the scheme, so that there is a very large amount of available clinical material. The classes and demonstrations are open to all qualified medical practitioners, and the teaching is conducted quite independently of the ordinary classes for students of medicine. The scheme for the summer course (May to October) is a very comprehensive one, including a wide range of clinical classes, but it also offers facilities in the form of clinical assistantships for those who may wish a more intensive study of one particular subject. The syllabus for these courses is now in the hands of the printer and will be available at an early date. Formerly during the winter (November to May) the only teaching facilities offered have been a series of weekly demonstrations, comprising medicine, surgery, and the various specialities. These will be continued during 1922-23, but in addition more systematized courses will be provided. The winter arrangements are not yet complete. The acting secretary for all these post-graduate courses is Dr. J. Norman Cruickshank, The University, Glasgow.

CHILD WELFARE INSTITUTE FOR SCOTLAND.

Progress seems at length to be assured in respect of the proposed Child Welfare Institute for Scotland. On July 30th, 1918, a conference was held in the City Chambers, Edinburgh, at which it was stated that the Carnegie United Kingdom Trust was prepared to establish in Edinburgh a Central Child Welfare Institute for Scotland, and the main functions of the institute were outlined; it was also stated that the Town Council of Edinburgh had heartily welcomed the Trust's proposal, and was of opinion that by the joint action of the local authorities of Scotland and others interested in the movement, with the co-operation of the Government, it should be possible to make arrangements for financing the institute. A provisional committee appointed at this conference has now issued a draft constitution for the organization of the institute; it recommends that the building, formerly known as James Gillespie's School should be acquired from the Edinburgh Education Authority, and makes proposals for providing the institute with the income necessary to enable it to carry on its operations. The Scottish Board of Health has informed the City of Edinburgh that it is competent for a local authority to make payments to the institute, and that the Board is prepared to sanction such payments as part of a child welfare scheme under the Notification of Births (Extension) Act of 1915.

GLASGOW ROYAL CANCER HOSPITAL.

The annual report of the Glasgow Royal Cancer Hospital, states that during the past year 205 patients had been treated in the hospital, and 40 in the out-patient department, while the district nurse had made 1,514 visits. The ordinary income amounted to £4,357, and the ordinary expenditure to £3,674, but the deficit was more than wiped out by extraordinary income in the form of legacies, etc. A new symmetrical x-ray instrument had been installed during the year, and important work was being carried on in the research department, under the auspices of the research committee, of which Professor Lt. Muir was convener. At the annual meeting of subscribers, held on March 23rd, Sir George T. Benson said that the hospital was setting a good example of co-operation, as scarcely a week passed in which they did not admit patients from the larger city institutions, such as the Royal, Western, and Victoria Infirmarys. Regarding the problem of cancer itself, he said that surgery could and did effect cure in the early stages of the malady, but a great many cases did not come under the view of the surgeon until they were beyond his assistance and had become inoperable; these mainly were the cases which came to the Glasgow Cancer Hospital. It was too early to speak of the results of the new symmetrical x-ray apparatus, but he could say that they were already such as afforded encouragement. The policy of the directors was that their funds should be devoted first to the immediate relief and care and treatment of the patients, and the residue should be devoted to research, but in order to develop the latter branch the directors had decided that there

should be a special research fund. He did not know of any object to which a man with riches could devote his money with better advantage to the community than in helping Scotland to take her share in the work of cancer research.

GLASGOW MEDICAL LUNCH CLUB.

The weekly meeting of this club on March 30th took the form of a general guest day, when a number of members took the opportunity of bringing with them one or more guests. In the absence of the president, Dr. F. R. Martin, Dr. David McKail occupied the chair. Amongst the guests was Mr. Logie, president of the Glasgow Rotary Club, and after lunch he addressed the members. Thereafter some discussion took place as to the advisability of continuing the weekly meetings during the summer months. Meantime it was decided to hold weekly meetings during April, leaving the matter of summer meetings to be decided later.

ANDERSON COLLEGE OF MEDICINE, GLASGOW.

There was a vacancy in the chair of medicine in this college, owing to the resignation of Dr. John M. Cowan. This has now been filled by the appointment of Dr. Hugh Morton.

Correspondence.

RICKETS.

SIR,—In a communication made by Professor D. N. Palon to the Glasgow Medico-Chirurgical Society, and published in abstract in the *BRITISH MEDICAL JOURNAL* of March 4th (p. 351), there occurs the statement:

"Recently an attempt had been made to prove that it [that is, rickets] was caused by the absence of a hypothetical antirachitic factor probably identical with the fat-soluble A substance. The author of this contention had now abandoned this view, and had reverted to the long-accepted theory that various errors of diet predisposed to rickets."

As a general rule, I think it is inadvisable for an investigator to reply to misstatements or criticism by correspondence independently of his scientific publications; but the above sentences, occurring in the medical press, and therefore read almost exclusively by medical readers who cannot have the opportunity of keeping in close touch with the details of all medical research, are so misleading that they demand my attention. For I understand that, although not referred to by name, I am the "author of this contention."

What I specially wish to deny is the statement that I have put forward certain views on rickets, and have now abandoned them. The sentences quoted above constitute, in my opinion, an example of both the *suggestio falsi* and the *suppressio veri*. They suggest that there has been a catastrophic break in my research on rickets involving the disproof of the main facts and the throwing over of ideas previously held and published by myself. This is an incorrect suggestion. They suppress the fact that even in my lectures on rickets in 1918 (*Lancet*, 1919, i, 407), although they only represented a summary of my work up to that time, I made it clear that rickets could not be regarded as a deficiency disease of the same nature as scurvy, for the accessory food factor which played an important part in the etiology of rickets was more influenced in its action by other elements of the diet and the environment than appeared to be the case with the antiscorbutic vitamin. In the second lecture of this publication I stated:

"For we know something of the part played by accessory food factors in such deficiency diseases as beri-beri and scurvy, and we know something of the part played by these substances in growth, but in the case of rickets we are apparently up against a combination of both deficiency disease and growth, rickets, in fact, being a disease accompanying growth."

Again, in the same lecture, I stated:

"Since, further, the dietetic problem is one of balance, food-stuffs which contain no antirachitic factor cannot be considered as neutral but as positively rickets-producing, for the more of them that is eaten the greater is the necessity for foods containing the factor. It is probable that bread is the worst offender."

Even the effect of exercise and its relation to the dietetic theory of rickets I mentioned in the first publication and discussed at greater length in the second publication (*Lancet*, 1920, i, 550), and the views on this point that I advanced then are substantially the same as I hold to-day. How near all these ideas approximate to my later views can be seen in my last and more complete publication on the subject of

rickets—namely, Special Report Series, No. 61, Medical Research Council.

Research has only touched the edge of the subject, and the amazing amount of work on rickets now being started in America and elsewhere may soon necessitate modification and extension of my published views as to the process of events occurring in this disease. It is possible that the deductions made from my experimental work on rickets may prove absurd, but I am not convinced that this has yet happened, nor have I seen any reason to abandon my earlier published views.—I am, etc.,

The University, Sheffield, March 28th.

EDWARD MELLANBY.

PROFESSIONAL SECRECY.

SIR,—At the Representative Meeting in 1921 a motion was carried:

That the Association use all its power to support a member of the British Medical Association who refuses to divulge, without the patient's consent, information obtained in the exercise of his professional duties, except where it is already provided by Act of Parliament that he must do so.

On a technical point this did not become the policy of the Association, but presumably this or a similar motion will again come up in July, 1922, with a view to its being adopted as the policy of the Association. It would be well, therefore, to examine the historic precedent for this attitude.

Reference was made, at the Representative Meeting of 1921, to the provision affecting professional secrecy contained in the Hippocratic oath, but its purport was, I think, distorted. In this oath, taken by members of the Asclepiad guilds about to be initiated into the art of medicine, and contained in the works of Hippocrates, the relevant clause runs as follows: *ἂ δ' ἂν ἐν θεραπείῃ ἢ ἰδῶ ἢ ἀκούσω, ἢ καὶ ἄνεν θεραπείης κατὰ β'ον ἀνθρώπων, ἂ μὴ χρή ποτε ἐκκαλέσθαι ἕω, σιγήσομαι, ἥρῃητα ἡγεύμενος εἶναι τὰ τοιαῦτα* ("Whatever things I shall see or hear in the course of practice or apart from practice relating to human life, which are not fitting to be proclaimed outside the house, I shall keep to myself, considering such things to be not matters for conversation").

The whole phraseology of the original, and especially the use of the words *ἐκκαλέσθαι* and *ἕω*, indicates that unwarrantable gossip about a patient's private affairs is the thing forbidden. There is no prohibition, either specified or implied, against revealing anything required for the public welfare.

The *Sponsio Academica*, which at certain universities is signed by the graduate when he receives a degree in medicine, is even more definitely prohibitive of idle talk regarding professional matters and permissive of their revelation when there is due cause, in the words: *Spondeo . . . quod, designum inter medendum visa vel audita sileri conveniat, non sine gravi causa, vulgaturum* ("I promise . . . that I will not make public, without serious reason, those things, seen or heard in my practice, upon which it is fitting to be silent").

The doctrine that a witness in a court of law, because he happens to be a medical practitioner, should decide what things are admissible in evidence and what are not admissible would appear to be one of very recent origin. Surely for practitioners would ask for better guidance as to what should be divulged or not divulged than the opinion of a judge who by his training and position, is specially skilled in the rule and proprieties of evidence.—I am, etc.,

JOHN D. COMRIE, M.D., F.R.C.P.

Lecturer on History of Medicine in the University of Edinburgh.

Edinburgh, March 30th.

RUPTURE OF EXTENSOR LONGUS POLLICIS TENDON.

SIR,—The correspondence on the above in the *Journal* would seem to indicate that this injury is not so rare as has hitherto been supposed.

In a pamphlet on *Colles's Fracture*,¹ published in 1921 I drew attention to this complication and cited the case of an old woman, aged about 70, who sustained a Colles's fracture and noticed when the splints were removed that she could not extend the distal phalanx of the thumb on the affected side. Four months after the accident I operated and found the tendon of the extensor secundi internodii pollicis (extensor longus pollicis) torn near the site of fracture. The distal portion of the tendon was united to the extensor primi internodii pollicis (extensor brevis pollicis) with a good functional

¹ *Colles's Fracture and other Fractures at the Lower End of the Radius and Ulna*. Belfast: Alex. Mayne and Sons, 1925.

sult. I attributed the rupture to trauma produced by the sharp edge of the lower fragment at the time of injury, and not, as Stapelmoir suggests in his cases, to necrosis and subsequent rupture of the tendon.

The pamphlet referred to was based on an account of twenty cases of fractures and disjunctions at the lower end of the radius and ulna read before the Ulster Medical Society during the session 1904-5, and published subsequently in the *Medical Press and Circular* (May 31st and June 7th, 1905).—I am, etc.,

Belfast, March 27th.

ANDREW FULLERTON.

ROUTINE PELVIMETRY IN ANTE-NATAL CASES.

SIR,—I read Dr. Thorne Thorne's letter (March 25th, 1922) on routine pelvimetry with appreciation; I also had thought that the value of such practices had impressed itself generally. At the same time I view with surprise Dr. Thorne Thorne's trust in the external conjugate. This I regard as the most fallacious of all the pelvic measurements. The fifth lumbar vertebra is frequently difficult to locate and the amount of soft parts covering it very variable.

I use the intercrural and interspinous measurements together with their ratio to determine whether I have to deal with (a) a normal pelvis, (b) a flattened pelvis, or (c) a generally contracted pelvis. More important still is the estimation of the internal or true conjugate. This is determined by subtracting $\frac{3}{4}$ in. from the diagonal conjugate as found by the examining fingers in the vagina.

In extension I endeavour to watch the advent of any lumbar complications by the routine monthly examination of the urine.—I am, etc.,

Woking, March 28th.

R. STAFFORD FOSS, M.B., B.S. Lond.

THE TREATMENT OF INSOMNIA.

SIR,—May I suggest that Professor Rudolf, in his article on the treatment of insomnia (*BRITISH MEDICAL JOURNAL*, March 11th), omits a therapeutic method of some importance, and one especially useful in the cases which fall within the groups presented in his first table. I refer to the use of high-frequency currents.

For twenty years I have found this method highly efficient in cases where insomnia is associated with a hypersensitive nervous system, dependent on such conditions as: neurasthenia, exhaustion, chronic toxæmia, or circulatory disturbances. I employ the currents either by the condenser couch or through the hand of the operator when it is used to apply massage particularly to the patient's back. Even when the currents are prescribed for reasons other than insomnia, it is frequent to learn from the patient that he is sleeping better, and in chronic cases of sleeplessness I know no more valuable remedial agency. In contrast to drug treatment, high-frequency currents produce no ill effects, and the sleep obtained is natural and refreshing.

In part no doubt by the removal of sleeplessness, and in part by their direct effects, the currents exercise a beneficial influence on the general tone of the nervous system, and depressing after-effects or other disadvantages are conspicuous by their absence. I trust this brief summary of my own experience may tempt some of my colleagues to put the issue to a practical test.—I am, etc.,

Glasgow, March 17th.

W. F. SOMERVILLE, M.D.

INSANITY AND THE ENDOCRINE GLANDS.

SIR,—The leading article in your issue of March 18th on insanity and the reproductive glands, associated with the publication last week of Sir Frederick Mott's lecture on the reproductive organs in relation to mental disorders, induces me to make public certain conclusions to which I have come as a result of the treatment of mental disease with the endocrine glands.

No one can doubt the pathological findings of such an authority as Sir Frederick Mott, whose work in connexion with the pathology of mental disease is recognized all over the world. At the same time one cannot close one's eyes to the fact that the reproductive organs are non-essential to mental health, and that therefore they cannot be the entire cause of dementia præcox. Indeed, the author acknowledges this by recognizing the presence of an "inborn germinal defect" in the majority of these patients. There is, further, the absence, so far, of any great clinical evidence that the medicinal administration of the reproductive glands will cure his condition. Dr. Ford Robertson—another distinguished

pathologist—has already published a list of cases supporting his hypothesis that dementia præcox is caused by microbe infection of the intestinal tract. He also holds, however, that there is an hereditary defect that makes this condition possible.

From the manner in which both manic-depressive insanity and the earlier cases of dementia præcox respond to treatment by thyroid extract, especially in those who have a psychopathic inheritance, I have formed the opinion that this inheritance is of a purely hypothyroidal nature. I hope to be able to publish some cases and arguments in support of this contention, and it is enough now to state that by judicious thyroidal treatment the illness of manic-depressive patients can be shortened to a marked extent, and, indeed, in some cases, aborted. In the earlier cases of dementia præcox a satisfactory result can also be obtained, and I hold that, if one could treat these patients with thyroid extract at a sufficiently early date, a very marked diminution of the population of our mental hospitals would become noticeable within a few years.

I should also like to point out that the inheritance in mental disease is not confined peculiarly to that abnormal state. It also covers many diseases that are known to have a certain familial relationship and at the same time an association with mental disease. In this connexion I would mention tuberculosis, the gonorrhoea, certain intestinal affections, and malignant disease. To me these and several other conditions primarily arise from a hypothyroidal state of the tissues upon which the more immediate cause of the particular disease is apt to flourish, and I believe that for a permanently successful result it is essential that this hypothyroidal state should be remedied.—I am, etc.,

St. Patrick's Hospital, Dublin,
March 27th.

H. R. C. RUTHERFORD,
F.R.C.S.I.

COMPARATIVE PATHOLOGY.

SIR,—The perusal of your leader in the issue of March 25th, 1922, in which some of the recommendations contained in the Report of the Advisory Committee on Research into Diseases in Animals are reviewed, urges me to refer to the work of the University of Liverpool in this subject.

In 1896 a medical graduate of this university, H. E. Annett, M.D., D.P.H., was awarded an 1851 Exhibition Scholarship and engaged in research at London and Berlin during 1897-99, on "the relationship of diseases of animals to those of man." Subsequently, during his association with the Liverpool School of Tropical Medicine, diseases of animals in tropical and subtropical countries were investigated. In 1904 Dr. Annett was appointed Lecturer in Comparative Pathology in the University of Liverpool with special laboratory accommodation, and Superintendent of the Farm Station of the Institute of Comparative Pathology (affiliated with the university) at Runcorn. From this nucleus the School of Veterinary Science in the university evolved, and in this school in 1906 the Lectureship in Comparative Pathology was elevated to a chair. After five years, however, owing to the lack of permanent endowment, the chair lapsed.

During the last ten years Dr. Annett has continued, as opportunity permitted, to maintain interest in this subject at the Runcorn Research Laboratories, and is at present engaged in similar research work in the university.—I am, etc.,

University of Liverpool,
April 3rd.

R. E. KELLY,
Dean of the Faculty of Medicine.

REDUCTION OF MEDICAL FEES.

SIR,—With interest and amazement increasing as I progressed, I read Dr. W. McD. Ellis's letter in the *BRITISH MEDICAL JOURNAL* of April 1st (p. 538). Possibly it was his realization that to-day would be Saturday, April 1st, and that the majority of us would be reading the *BRITISH MEDICAL JOURNAL* with our breakfasts this morning, that explains the presence of his letter. I cannot bring myself to believe that it is intended to be taken seriously.

When the cost of living began to rise I think it rose for the doctor as well as for his patients, with this difference, however—the average patient got a war bonus or increased wage, or both, to compensate him much earlier than his doctor. When the doctor did get his belated increased fee it was only a 50 per cent. increase, and, as Dr. Ellis says, the cost of living was at high-water mark. At that time I think I am right in saying that a £1 note was worth about a pre-war 8s. 6d., so that a 50 per cent. increase hardly squared things for us. The cost of living appears to me to be still well above 50 per

cent. more than in pre-war days, so why should the profession decrease their fees? When the cost of living sinks below that mark—50 per cent. above the pre-war level—we might pause to consider Dr. Ellis's suggestion, but even then should we decrease? Were some doctors' fees in pre-war days just recompense for their services?

A certain standard of efficiency is demanded of us by the community, certain expenses have to be met in attaining that standard, and further expenses in obtaining a practice. From a business point of view one wants a fair wage for one's services, plus a fair return on the capital expended and invested.

I believe that to this standard of efficiency little additions are made on frequent occasions, such as optional subjects becoming compulsory; a minimum of four increasing to five years of study after registering as a medical student; the abolition of unqualified assistants, etc.

Have fees charged kept pace with those demands upon us? How long is it since doctors increased their fees previous to this occasion under discussion? I do not know, but I think I recollect reading that medical men charged half-crown and guinea fees during the reign of Queen Anne. In any case those two figures have had a pretty long reign, and the cost of living must have undergone several increases since they were instituted, apart from the possibility of medical practitioners increasing 50 per cent. in efficiency during the last couple of generations. Yet many a doctor to-day receives 2s. 6d. per visit and 3s. 6d. per bottle of medicine; surely that is little enough.

Then, again, there are the ex-service men. Some had practices which they sold for a song, and they joined up. Others had taken out extra classes and extra degrees, hoping to specialize, but instead they joined up. Now both these are trying to settle into practice, wishing that some of this money which it worried them so little to sacrifice had not slipped away. As it is their gratuities, together with gifts and loans from parents, have been recently invested in practices whose prices had become inflated much above their 1914-17 values. At that period many a man had no choice but to sell or leave his practice, to the advantage of those unfit for service. Thus they now lose capital a second time.

I wonder how many of these subtracted the amount of the panel cheque just arrived from that for last quarter, thinking "Yet another injustice to the ex-service man, and the ex-charge given for it was 'patriotic reasons.'" Dr. Arthur T. Todd-White's letter in the SUPPLEMENT of this same date will harmonize better with their sentiments than Dr. Ellis's letter.

We ex-service men have learnt to suffer much in silence, but one at least cannot stand by whilst a medical practitioner takes the initiative in dealing the profession another blow which hits us hardest of all its members. Probably Dr. Ellis is well under way with life's race, and therefore has lost sight of us who are taking our places at the start, so full of indignation over our present handicap to be in no mood for considering a further increase of it.—I am, etc.,

Standish, Lancs, April 1st.

T. WILSON SHAW.

SIR,—While the reduction of medical fees that Dr. Ellis recommends may be advisable in better-class practices, I consider it decidedly inadvisable in the case of the private practice of a panel practitioner.

A few months ago the maintenance of our private fees at their present level was assured us and advanced as an inducement to us to submit to the recent reduction in the panel capitation fee. The relatively higher remuneration of private practice I consider to be most valuable both as a stimulus to sound careful work and as a discouragement for any man to develop his panel, with all the degradation and perfunctory dexterity it entails, at the expense of his private work, in which competition, if fair, is so healthy and stimulating.

The effect on the lay public also will be equally beneficial and salutary.—I am, etc.,

Dukinfield, April 2nd.

JAMES BRIERLEY, M.D.

SIR,—In your issue of April 1st one correspondent takes the view that every medical man is worth £2,000 per annum—he does not say whether he means net or gross. Another suggests that the Association give a lead in the way of reducing fees—as some time since they advised their being raised by 50 per cent. I feel gratified to be told I am worth so much, and only wish I could make it—even gross at 4s. for surgery advice and 4s., 5s., up to 7s. 6d. and 10s. 6d. per visit

—the last figure a rarity. I hope the Association will make no move in the matter. It is a question of supply and demand largely. The Government have docked from those who have a panel more than they had reason to, never having given them their full due.

I have been twenty-eight years in practice very nearly, and patients are not disposed to pay me more than 2s. 6d. or 3s. 6d. they must go elsewhere, and I shall be left more leisure—at little the poorer. If a young opponent thinks he can gather my expense by the process known as "undercutting," well, I must do it. But I don't see why the British Medical Association should help him, nor why they should give the public thick stick to beat me with.

As regards the alleged "unpopularity" of doctors I have not yet experienced it, or I may be too innocent to see it. I do not work in an industrial district, however, I must admit I think the lead of the Association as to raising fees by 50 per cent. was adopted by few to the full extent or any!—like it—I am, etc.,

April 3rd.

M.D.

VENEREAL DISEASE.

SIR,—Mr. E. B. Turner and Mr. Charles Gibbs declare that as far as self-disinfection is concerned, they confess themselves "unimpressed" by the data so far published. I think that we should have collected the figures ourselves and that "an independent expert in statistics" would have reached different conclusions. But how could we collect the figures, and why would statistics collected by us be especially impressive? The statistics which they find unimpressive were collected in the ordinary course of duty by naval and military medical officers. In each case the officer had many men (an army corps, or the troops in a complete English counties, or a regiment, or a group of battalions or a ship) in charge; so many cases of venereal disease occurred among them during such and such a length of time, therefore the venereal rate per 1000 per annum was such and such. These are the figures which, according to the thinking of Mr. Turner and Mr. Gibbs, call for "an independent expert in statistics." What scope is there here for a statistician, however "expert"?

For two years the troops in Reid's medical charge, along with him on the average for many months—on garrison duty or undergoing training. Then his barracks, which had emptied somewhat during the German offensive, were swamped with troops from overseas—highly infected birds of passage. But his figures do not stand alone. Disease contracted by the instructed men sank in the whole area to the vanishing point.

When confronted with figures, all of which can be tested from official records, Mr. Turner and Mr. Gibbs are "unimpressed"; but surely the important point is that a "pledge that disinfectants will disinfect has been sworn broad-cast over the empire. The work is done, and will certainly prevail against all obstacles, governmental or otherwise. We are, etc.,

H. BRYAN DONKIN,
G. ARCHDALE REID.

London, March 29th.

THE CONFERENCE OF STAFFS OF HOSPITALS.

SIR,—Dr. Garratt of Chichester appeals to me for help in difficulty. He thinks there is an inconsistency between two of the leading recommendations of the Council on the organization of voluntary hospitals, both of which were passed by large majorities at the recent conference of staffs of voluntary hospitals. He suggests that the approval of the definition for the transfer of a percentage of the payments of patients of these hospitals to the staff fund (par. 33) is incompatible with the approval of the definition which claims the essence of the voluntary hospital system is its independent and voluntary management (par. 7). He asks, How can we claim recompense for our own services and deny the same to the management? I have re-read the report and I fail to find any statement or implication that the management should be paid or unpaid. Dr. Garratt's difficulty arises from his attaching to the word "voluntary" the meaning unpaid, a meaning it does not necessarily bear. It would be easy to cite a dozen conditions in which voluntary hospitals are paid and unpaid. Has Dr. Garratt already forgotten the unique voluntary effort in which hundreds of thousands of our countrymen flocked to the national standards? Did he deny these men their proud claim to be volunteers and not conscripts because they received pay and allowances according to scale? Probably in the generosity of his heart he would have wished for them double the pay of the conscript.

We define the voluntary hospital system as independent and voluntary, not in relation to money but to control. The state hospitals are established and maintained under the authority of Acts of Parliament; their provision is obligatory, and the local and central authorities have powers of control. Voluntary hospitals are free, both from statutory obligation and control. The point was clearly in the mind of the Conference; indeed, one representative urged that there should be added to the definition words declaring this freedom; but the suggestion was rejected, for there are other forms of control that may threaten the independence of the voluntary hospitals even more than State or municipality.—I am, etc.,

London, W., March 31st.

N. BISHOP HARMAN.

REMEDIAL EXERCISES IN SCOLIOSIS.

SIR,—In the report of the proceedings of the Orthopaedic Section of the Royal Society of Medicine, appearing in the *BRITISH MEDICAL JOURNAL* of March 18th on the above subject, I looked in vain for reference by any of the speakers to Professor Sherrington's recent epoch-making discoveries on the "postural contraction of muscles." In such a static condition as scoliosis these discoveries most particularly apply; in fact, they revolutionize the old-fashioned exercises referred to by most of the speakers.

The absence of any reference to this physiological discovery anent muscle function is proof positive that a revision of the present methods of remedial exercise treatment is urgently needed.—I am, etc.,

Liverpool, March 23rd.

W. H. BROAD.

Obituary.

W. AINSLIE HOLLIS, M.D., F.R.C.P.,

Consulting Physician to the Royal Sussex County Hospital, Brighton; late President of the British Medical Association.

WE announced last week with much regret the sudden death, at Hove on March 26th, of Dr. W. Ainslie Hollis, who was President of the British Medical Association when it met at Brighton in 1913. Although in his 83rd year, Dr. Hollis seemed in good health, and in spite of the cold weather had taken his usual tricycle ride on the previous day.

William Ainslie Hollis was born in 1839 at Lewisham, where his father, Dr. W. M. Hollis, had a large and arduous practice. From Brighton College he went to Trinity College, Cambridge, and graduated B.A. in the Classical Tripos, becoming M.A. in 1865. His medical education was received at St. Bartholomew's Hospital, where he held in turn the offices of house-physician (being one of the first to be appointed after the abolition of the post of hospital apothecary), medical registrar, and casualty physician. His colleagues among the house-physicians first appointed in 1867 included Dr. Philip Hensley, afterwards physician to the hospital, and also a Cambridge man. Hollis graduated M.B. in 1867 and M.D. in 1871. In accordance with the wish of his father, who did not think him robust enough for general practice, he decided to become a physician, though Sir George Humphry, with whom he worked for a short time in Cambridge, had tried to persuade him to take up surgery. He was a candidate for the post of assistant physician to St. Bartholomew's Hospital when Sir Lander Branton was elected. At that time he was investigating the nature of inflammation and the causation of atheroma and arteritis, and is said to have been one of the first to use a clinical thermometer in the wards of St. Bartholomew's. The short clinical thermometer, it will be remembered, was introduced by Sir Clifford Allbutt in 1868.

In 1874 Hollis went to Brighton, where he was soon elected assistant physician to the Royal Sussex County Hospital. He subsequently became full physician, and finally, on his retirement from the active staff, honorary consulting physician. He was elected a Fellow of the Royal College of Physicians of London in 1876. His private practice was never large, his work tending more towards literary and scientific subjects. He became President of the Brighton and Sussex Medical-Chirurgical Society and of the Brighton Natural History and Philosophical Society, and his fine collection of British macrolepidoptera was presented by him to the Hove Public Library.

Dr. Ainslie Hollis was a loyal and active member of the British Medical Association, and those who attended the Annual Meeting at Brighton nine years ago will remember that its great success was largely due to the efforts of the President, who, although at that time getting on in

years, worked hard for months beforehand to ensure this result. He attended the opening meeting of the Representative Body, and all through manifested the greatest interest and activity in all the arrangements made to ensure the instruction and entertainment of the visitors. At the conclusion of the meeting he accepted an invitation from the Eastbourne Division to join a series of excursions in that town, which occupied the whole of the day, and responded to the toast of the British Medical Association at the lunch given by the Association. His Presidential Address on "The medical history of Brighton" was a scholarly production worthy of the high office he held; it was printed in full in the *BRITISH MEDICAL JOURNAL* in August, 1913. During the week he gave a series of lunches to the medical visitors from all parts of the country, and his numerous guests bore witness to his hospitality. He was present at all kinds of functions and discussions during the ten days of the Annual Meeting, and entered fully and heartily into the social, scientific, and business sides of the meeting. At the reception given by the President and the Division at the Hove Town Hall, where he was assisted by Mrs. and Miss Hollis, Dr. Hollis welcomed the many guests individually. Altogether he helped to make the Annual Meeting of 1913 a great and remembered success. As a token of the respect and esteem in which he was held by his colleagues he was presented just before the delivery of his Presidential Address with a replica in gold of the President's badge of office.

Dr. Hollis took his part in municipal work. In 1890 he was elected a member of the Hove Commissioners, on which body he served for eight years. Later, when the Borough of Hove was incorporated, he was elected a member of the Town Council, and served on the Technical Instruction and Library Committees; in the work of the latter he was particularly interested. He was a good classical scholar; he read Latin as fluently as English, and could translate Spanish and Italian with ease, though he had never learnt those languages. His commentary for the M.R.C.P. diploma was written in Latin. His published books and papers include "Among the Tetebas in Central Asia" (a work of fiction much on the lines of Rider Haggard's "She," which was published soon afterwards), "How to avoid a common cold," and also many papers in the *British Medical Journal*, the *Lancet*, the *Journal of Anatomy and Physiology*, the *Journal of Pathology and Bacteriology*, and elsewhere, including contributions on "The joint of a fowl's tongue and its vocal function," "Disseminated fibrosis of the kidney," and "The duration of life in infective endocarditis." Among his hobbies were cactus growing, photography, and cycling. The versatility of his character is further shown by the fact that he drew the plans and superintended the building of the house he dwelt in during the last ten years of his life.

The following notes on matters connected with his father's work, by his son, Dr. S. Hollis, may be added to complete the memoir:

A point of some interest is the fact that in 1852 my father and grandfather were in Paris. My father told me how the clotted blood remained on the mould round the trees in the streets after Napoleon III's friends carried out the coup d'état by which President Buonaparte became Emperor. When a student (students visited patients then) he sat up at night with a woman suffering from hæmorrhagic small-pox during the epidemic in London, her appearance being such that no one would go near her except one old woman who had had small-pox and who was off duty that night. After being house-physician at Bart's he held the same post at Victoria Park Hospital, and an epidemic of cholera visited London during that period. Soon after this he advanced the suggestion that inflammation (including sequelæ such as fibrosis) was a local condition independent of the central nervous system, and showed that it could occur in a severed limb, such as a lizard's tail. Later he developed this idea in his writings on arterial, renal, and cardiac disease, holding that atheroma is a local disease, although a widespread one; that arteritis may be due to poison produced within the system or, as in the case of lead poisoning (much commoner in those days), introduced by the mouth, but in both cases acting locally on the arterial wall while circulating in the blood stream.

The funeral services took place at the Brighton parochial cemetery on the afternoon of March 30th, and the interment afterwards in the family vault. Dr. E. R. Fothergill represented the Council of the British Medical Association. Dr. Sanderson and Dr. L. A. Parry the Brighton Division of the Association, and Dr. Whittington the Sussex Medico-

ROYAL COLLEGE OF SURGEONS IN IRELAND.

The following candidates have been approved at the examinations indicated:

PRIMARY FELLOWSHIP.—Miss Attracta Halpenny, S. O'Neill, C. J. A. Woodside.

FINAL FELLOWSHIP.—E. D.A. McClea.

CONJOINT BOARD IN IRELAND.

The following candidates have been approved at the examinations indicated:

FINAL PROFESSIONAL EXAMINATION.—T. A. Bennett, W. A. Benson, P. P. Connolly, Mrs. Michael Brendan Devano, Dorothy H. Douglas, J. Eliassoff, C. J. Ellison, C. V. Falvey, S. Griffin, A. Hazman, H. Levinson, H. J. Mulligan, Anna J. O'Reilly, R. B. Shaw, R. Szeowitz, H. L. W. Water.

D.P.H.—Dr. V. R. O'Connor.

UNIVERSITY OF LONDON.

Correction.—In announcing last week p. 514 the conferment upon Miss E. E. Hewer of the degree of D.Sc. in Physiology by the University of London, the recipient should have been described as an internal student of the London (Royal Free Hospital) School of Medicine for Women, and not an internal student of Bedford College, as printed.

The Services.

HONORARY PHYSICIANS TO THE KING.

The following appointments of honorary physicians to the King are announced: Major-General A. P. Bleukinsop, C.B., C.M.G., late R.A.M.C., vice Colonel E. Eckerley, retired, and Lieut.-Colonel and Brevet-Colonel Sir E. S. Worthington, K.C.V.O., C.B., C.I.E., R.A.M.C., vice Major-General J. J. Gerrard, C.B., C.M.G., retired.

ARMY MEDICAL LIBRARIES.

The War Office announces that it has been decided to establish in the principal military hospitals at home and abroad small libraries of standard books of reference and of current medical literature, in order that officers of the Royal Army Medical Corps may be able to keep themselves informed of advances in medicine and the allied sciences. Each library will form a medical intelligence bureau for the district which it serves and be available for all officers of the corps serving in that district.

Libraries at home stations will be supplied (at the public expense) with Rose and Carless's *Manual of Surgery*; Oster and Macrae's *Principles and Practice of Medicine*; Parkes and Keenwood's *Hygiene and Public Health*; Maunsell's *Tropical Diseases*; British *Journal of Surgery*; *Journal of Hygiene*; *Medical Abstracts and Reviews*; *Tropical Diseases Bulletin*, and standard works on medical and allied sciences to the total value of £5 annually. The libraries at stations abroad will be supplied with all the above works and periodicals, and, in addition, Howland and Turner's *Operations of Surgery*; Stitt's *Practical Bacteriology*; Alcock's *Entomology for Medical Officers*; and Hutchison's *Diseases of Children*. Standard works will be allowed up to the value of £9 annually.

Each library will be placed under the care of an officer to be selected by the Deputy Director of Medical Services of the command from the staff of the hospital in which the library is situated.

FOREIGN DECORATIONS.

The following are among the decorations awarded by the Allied Powers for distinguished services rendered during the war.

By the King of the Belgians.—Ordre de Leopold—Officier: Colonel Charles . . . Canadian Army Medical Corps.
Ordre de . . . Brevet Colonel James Paul Bush, C.M.G. . . T.F.

By the French Republic.—Légion d'Honneur—Chevalier: Temporary Captain Charles Gerald Harmer, R.A.M.C.
By the King of Italy.—Silver Medal, "Al Merito Della Sanità Pubblica": Major-General Sir F. R. Newland, K.C.M.G., C.B.

Medical News.

At the Aberdeen University graduation ceremony on March 30th the honorary degree of LL.D. was conferred upon Professor Thomas Wardrop Griffith, C.M.G., M.D., F.R.C.P., professor of medicine in the University of Leeds.

The Morison lectures before the Royal College of Physicians of Edinburgh will be delivered by Professor G. Elliot Smith, F.R.S., on May 1st, 3rd, and 5th, at 5 p.m.; the subject is *The Evolution of the Human Intellect*.

At a meeting of the Central Midwives Board for England and Wales, held on March 23rd, with Sir Francis Champneys in the chair, four midwives who had been cited were struck off the Roll.

The inquiry of the Mosquito Investigation Committee of the South-Eastern Union of Scientific Societies into the habits of *Anopheles plumbeus* was hindered by the drought of last summer. It is proposed to resume the investigation, and information as to the particulars required can be obtained on application to the Rev. T. W. Oswald-Micks, Lesware, Linton Road, S.E.15.

In Sweden, according to a recent decision of the Lower Court of Appeals at Stockholm, medical practitioners cannot in future be compelled to give evidence in court against their will in cases with which they have been professionally connected.

The Rockefeller Foundation has given 6,000,000 dollars to the Johns Hopkins University for the school of hygiene and public health; of this sum 1,000,000 dollars is to be available for the erection of new buildings for the school and 5,000,000 dollars for an endowment covering its maintenance. Work on the main building is expected to start this summer.

ARRANGEMENTS have been made for six lectures to be given, in English, by English lecturers, in the grand amphitheatre of the Faculty of Medicine of Paris: on May 6th Sir Sidney Russell-Wells will lecture on the circulatory effects of mitral stenosis and aortic regurgitation; on May 11th, Sir Wilnot Herrington, on trench fever; on May 13th, Dr. Sampson Handley, on lymphatic pathology, with special reference to malignant disease; on May 18th, Professor E. H. Starling, on the mechanism of compensation in the heart; on May 20th, Mr. H. J. Waring, on acute pancreatitis, its diagnosis and surgical treatment; on May 27th, Professor G. Elliot Smith, on stereoscopic vision and the evolution of man.

DR. BEDFORD PIERCE, on the occasion of his resigning the post of medical superintendent of the York Retreat Mental Institution, has been presented with many farewell gifts, including cheques of £105 and £100 from the committee and past and present members of the staff respectively, a portrait in oils of himself as a personal gift from the committee, with a replica to hang in the board room. He has been appointed consulting physician to the Retreat. Mrs. Pierce has also received a number of gifts.

At the annual meeting of the Society for the Study of Inebriety to be held at 11, Chandos Street, W.1, on Tuesday, April 11th, at 4 p.m., Dr. Edgar L. Collins, Talbot professor of preventive medicine in the University of Wales, will open a discussion on the use of alcohol by the industrial worker.

The King has approved the appointment of Lieut.-Colonel James Young, M.D., T.D., as a deputy lieutenant for the county of Gloucester.

The first three Friday evening discourses after Easter at the Royal Institution of Great Britain will deal with medical or biological subjects. On April 28th Professor Arthur Harden, F.R.S., head of the Biochemical Department, Lister Institute, will speak on vitamin problems; on May 5th Dr. Michael Graham will describe some of his biological studies in Madeira; and on May 12th Dr. H. H. Dale, F.R.S., director of the Department of Biochemistry and Pharmacology at the National Institute for Medical Research, will discuss the search for specific remedies. On June 9th Mr. Joseph Barcroft, F.R.S., reader in Physiology in the University of Cambridge, who has recently paid a visit to the Andes in company with Professor Meakins of Edinburgh, will relate some of the results of their investigations into the physiological effects at high altitudes. The discourses will be given at 9 p.m.

The report presented at the annual meeting of the Cremation Society of England on March 29th showed that the number of cremations in Great Britain in 1921 was 1,922, about 100 below the maximum figure which was reached two years ago. Altogether, since the opening of the first crematorium at Woking in 1835, there have been 25,418 cremations. Nearly half the cremations take place at Golders Green; but there are thirteen other crematoriums in England and one in Scotland, and other schemes for erecting crematoriums are well advanced, especially one at Pontypriid. According to one speaker at the annual meeting (Mr. A. E. Bernays), every thousand ordinary burials in single graves occupy an acre, so that the encroachments of the cemetery in urban districts, if the present method of disposing of the dead continues, can be forecasted. The practice of cremation, so far from destroying sentiment, would make it possible to revert to the old practice of intramural interment. Sepulture in churches would no longer be forbidden by sanitary law, and Westminster Abbey, where few or no more bodies can be buried, might continue indefinitely to receive the cremated ashes of famous men and women. The Cremation Society, which has recently changed its address to 52, New Cavendish Street, W., has a life membership scheme which includes the prepayment of cremation fees, and this is an advantage, especially in the provinces, where cremation fees are higher than in London owing to the comparatively small number of cremations which are carried out.

There was a slight increase in the number of deaths from influenza in the week ending April 1st; the figures for the 105 great towns were 113, as against 104 in the previous week; and for London 21, as against 17.

At the meeting of the London County Council on April 4th Dr. Edward Mapother, deputy medical superintendent of the Long Grove Mental Hospital, was appointed medical superintendent of the Maudsley Hospital. Each candidate for the post was informed that the appointment would be held subject to the pleasure of the Council, which would be exercised at the expiration of six years at latest. The salary is to be £900 a year, on a pre-war basis, and the approved temporary additions bring the amount up to £1,200 a year. It is understood that the superintendent is to be permitted to practise as a consultant so far as this is consistent with his duties at the hospital. In the selection of the candidate two eminent psychologists, nominated by the University of London, gave the Asylums Committee the benefit of their views.

The North-East London Post-Graduate College will hold a special intensive course at the Prince of Wales's General Hospital, Tottenham, N.15, from Monday, May 15th, to Saturday, May 27th, inclusive. It will include demonstrations, in the mornings, of clinical and laboratory methods, groups of illustrative cases, etc., and on Saturday mornings practical demonstrations in associated hospitals. The afternoons will be devoted to general hospital work with clinics in the various departments, which will be followed each afternoon by a clinical lecture dealing more especially with the treatment of disease. The first of the series of clinical lectures will be given by Sir Thomas Horder, M.D., on "Some clinical types of arthritis and their treatment." Luncheon will be obtainable in the neighbourhood of the hospital, and tea will be provided each day. It is expected that the syllabus will be available before Easter.

The membership of the Tuberculosis Society of Scotland is now nearly 70; the President for the current session is Professor Sir Robert Philip, P.R.C.P. Edin., the honorary secretaries are Dr. W. Leslie Lyall and Dr. Ian Struthers Stewart, the honorary treasurer is Dr. Macrae Taylor, and the Editor of the Transactions Dr. A. Fergus Hewat. The Society holds regular meetings for discussion; the next will take place on Friday, April 28th, at 4 p.m., in the New University Buildings, Edinburgh.

The house and library of the Royal Society of Medicine, Wimpole Street, W.1. will be closed from Thursday, April 13th, to Tuesday, April 18th, both days inclusive.

Letters, Notes, and Answers.

On account of printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

Persons desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Atiology*, Westrand, London; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate*, Westrand, London; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Medisecra*, Westrand, London; telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 15, South Frederick Street, Dublin (telegrams: *Bacillus*, Dublin; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate*, Edinburgh; telephone, 4361, Central).

QUERIES AND ANSWERS.

INCOME TAX.

"P. S." has ceased to use his own car and is hiring from a job-master as occasion requires. Has he any claim in respect of the loss incurred in connexion with the former purchase of his now useless car?

No. A claim to depreciation cannot be made in connexion with an assessment of professional as distinct from trade profits; he is entitled to the cost of replacement only, and in the circumstances there was no such outlay. The point was raised before the Royal Commission on Income Tax, and that body recommended that this distinction should be abolished, but that has not yet been effected. With regard to the purchased premises, "P. S." can deduct in lieu of the rent the amount on which he is assessed to Property Tax—that is, Income Tax Sch. A.

LETTERS, NOTES, ETC.

SLIPPING RIB.

Dr. EDGAR F. CYRIAX (London, W.1) writes with reference to Mr. R. Davies-Colley's communication on slipping rib (March 18th, p. 432), to point out that this condition of the rib has been described by him in the *Practitioner* for June, 1919, and also that Stiller (*Die asthenische Konstitutionskrankheit*, 1907) essayed under this title to establish a clinical entity one of whose most constant symptoms was looseness of the tenth rib.

COUÉ AND DUBOIS.

Dr. N. W. MARKWELL (London) writes: M. Coué has recently been credited with bringing forward a new principle in connexion with his so-called "Law of Reversal of Effort." The name and explanation of the mechanism involved are new, but the description and the use of the mechanism are not. Professor Paul Dubois (*The Psychic Treatment of Nervous Disorders*, English translation by Jelliffe and White, 1907) enunciated the mechanism clearly enough for others to grasp it and to use it in practice. It is a main feature in his persuasive method. . . . The whole book expounds this mechanism. For example (p. 155) he states: "If we can, by a healthy philosophy of life and by moral hygiene suppress this toxic element of emotion we shall rid the greatest physical and intellectual fatigue of its harmful influence." In this and other passages Dubois points out unequivocally that a fundamental psychological principle which is of the greatest utility in practice does exist. One may not agree with Dubois's psychology and metaphysics, nevertheless we are in his debt, and not in the debt of M. Coué. For some years I have been in the habit of designating the mechanism "The Positive Reaction."

ASCULAPIUS AND CONSUMPTION.

Mr. MORLEY ROBERTS (London) writes: Doubtless most physicians have read Sir Thomas Browne's *Religio Medici*, and it is possible that some may even have looked into his essay entitled *On Dreams*, but I have never seen any comment on the passage in the latter piece which runs: "And a man might be hard put to it to interpret the language of Asclepius, when, to a consumptive person, he held forth his fingers, implying thereby that his cure lay in dates, from the homonymy of the Greek, which signifies dates and fingers." As our learned author does not quote his authority, it is hard to say where this comes from, but it seems capable of an interesting interpretation. As Hippocrates was of the family of the Asclepiadae, one of whose chief seats was Cos, this saying may possibly be found in his works or the pseudo-Hippocratic writings. Perhaps some student of Hippocrates can tell me if this is so. It seems to me that this cryptic saying may be regarded as sound advice. Suppose that the physician's comment was, "By this I do not mean dried dates but fresh ones. Go where you can get them daily. I suggest Egypt as the handiest place where the date tree flourishes." If my suggestion is correct one may infer that modern doctors, when they recommend the dry, pure desert air, are but following, without knowing it, the advice of some unknown Greek colleague, unless Browne really meant Hippocrates when he wrote of the mythical Asclepius.

FIRST AID TO THE INJURED.

SQUADRON LEADER W. ROSS KEMP, R.A.F.M.S., writes to call attention to the fact that the present edition of the St. John Ambulance Association's *First Aid to the Injured*, which has been rewritten by Dr. R. Bruce, was originally compiled by the late Surgeon-Major Peter Sheppard, R.A.M.C., who was killed at the Battle of Isandlwana, Zululand, in 1879. Our correspondent considers that this small volume, which has been the origin and foundation of all first aid work, ought still to retain, as a lasting memorial to him, the original author's name, which, he says, used to appear in the earlier editions.

VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 32, 33, 36, 37, 38, and 39 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 34 and 35.

The following appointments of certifying factory surgeons are vacant: Brynmawr (Brecon), Carlisle (Cumberland).

SCALE OF CHARGES FOR ADVERTISEMENTS IN THE BRITISH MEDICAL JOURNAL.

	£	s.	d.
Six lines and under	0 9 0
Each additional line	0 1 6
Whole single column (three columns to page)	7 10 0
Half single column	3 15 0
Half page	10 0 0
Whole page	20 0 0

An average line contains six words.

All remittances by Post Office Orders must be made payable to the British Medical Association at the General Post Office, London. No responsibility will be accepted for any such remittance not so safeguarded.

Advertisements should be delivered, addressed to the Manager, 429, Strand, London, not later than the first post on Tuesday morning preceding publication, and, if not paid for at the time, should be accompanied by a reference.

NOTE.—It is against the rules of the Post Office to receive replies to letters addressed either in initials or numbers.

EPITOME OF CURRENT MEDICAL LITERATURE.

MEDICINE.

325. Yeast Infections of the Skin.

GREENBAUM and KLAUDER (*Arch. Derm. and Syph.*, March, 1922), review the literature on yeast infections of the skin, and describe seven cases investigated by themselves. Since yeast cells are known to be normally present on the skin they controlled their observations by a study of the saccharomycetous flora of the normal skin, during which 150 unselected persons were examined and cultures made from healthy epidermis. Yeasts were obtained from thirty-five individuals, and were classified according to their cultural reactions and divided into four groups, three of which were true saccharomycetes, showing budding forms with asci, and one a cryptococcus, asci not being found. The seven cases of infection due to yeasts were characterized by a dermatitis involving the interdigital spaces (intertrigo saccharomycetica), and from all of these yeast cells of one or other of the four types above mentioned were recovered by culture. The pathogenicity of these organisms was proved by inoculation of guinea-pigs, and in one case by auto-inoculation of the human subject. Clinically, the authors describe two types of lesion in their cases of intertrigo saccharomycetica—one a dry lesion showing a bright red dermis beneath a smooth, thinned, glistening epidermis, and the other an accumulated mass of undermined sodden epidermis, moist and white in colour. These cases presented an exact resemblance to ringworm infections in the same locality, but, in spite of repeated examinations, no fungi other than the yeasts were found. It would seem, therefore, that yeast cells, like cocci which are normally found on the skin, may under certain conditions become pathogenic and cause a superficial infection. These lesions were found to be easily cured by the application of 10 per cent. tincture of iodine or 1 per cent. chrysarobin ointment, provided the skin was kept dry—a most important point. WEIDMAN, in the same journal, in an article entitled "Resemblances of yeasts in cutaneous scrapings to hyphomycetes," describes how in three cases of scrapings from the skin he observed mycelial filaments under the microscope which gave cultures, not of ringworm as expected, but of yeasts. Under unfavourable conditions these yeast fungi may develop a mycelium in the skin which renders it impossible, with the aid of the microscope alone, to place the organism in its correct order.

326. Physical Estimate of Malarial Disability.

MACDONALD (*Journ. R.A.M.C.*, February, 1922), believing that there are physical data readily obtainable in cases of men invalided for malaria, sufficient to establish their fitness or otherwise for work, examined 172 authenticated malaria cases under treatment at a command dépôt, such examination having been ordered to ascertain whether they were fit for a command dépôt or should be returned to hospital. Of these, 155 were found to be fit to return to their units, 17 being fit for the command dépôt. Malarial parasites were found in three cases only. Emphasis is placed upon the inveteracy with which malaria has hitherto been considered a disability, regardless of the absence of actual disablement, and often without specific evidence of infection; the acceptance of paleness as synonymous with anaemia, and the infrequency of haemoglobin estimation as a criterion of health, are deprecated, and it is urged that certain physical data allowing of accurate estimation should be taken as the basis of a just estimate of fitness or unfitness. Apart from temperature and blood examination, stress is laid upon the spleen and the haemoglobin records, enlargement of the spleen being indicative of extensive infection. Of the series ten spleens were just palpable (+1), one was apparently enlarged (+2), but none were greatly enlarged (+3). In only 23 of the men was the haemoglobin index 75 per cent. or under, the remainder being 80 per cent. or over.

327. The Parkinsonian Syndrome in Epidemic Encephalitis.

DE LISI (*Il Policlinico, Sez. Med.*, November 1st and December 1st, 1921) records 10 cases, 6 of which were in males and 4 in females, aged from 13 to 39. Nine had suffered from epidemic encephalitis in the winter of 1919-20 and one in the winter of 1918-19. In six at least of the cases the disease in its initial stage was of the ordinary oculo-letargic type. As a rule an interval of relatively good health had intervened between the acute attack and the development of the Parkinsonian syndrome. No gross palsies were present, but

only slight paresis of the fifth and seventh nerves. The predominant symptom was extrapyramidal muscular rigidity, bradykinesia, and restriction of muscular movement. Almost all the patients showed katatonic movements—that is, a tendency to maintain a posture actively assumed—and only a few showed catalepsy. Ataxia was not found, but retropulsion and pseudo-adiadochokinesia were frequent. Choreic and athetotic movements were absent. The typical Parkinsonian tremor was always absent. Either there was an absence of any tremor or there was a tremor caused by intestinal movements, passive postures, or without any appreciable cause. The only symptom of objective sensibility was a zone of superficial hyperaesthesia which was found in one case in the area of the tenth dorsal nerve on one side. The cerebro-spinal fluid was always normal. The oculo-cardiac reflex was usually exaggerated. None of the therapeutic measures employed had any effect. Intravenous injection of sodium cacodylate in large doses, recommended by some writers, did not produce even temporary improvement, but, on the other hand, no bad effects were observed. The Parkinsonian syndrome of epidemic encephalitis is not entirely identical with the classical syndrome of paralysis agitans, but bears a very close resemblance to *paralysis agitans sine agitatione*, which is an exceptional variety of the Parkinsonian syndrome.

328. Antiscorbutic Value of Dried Fruits.

EXPERIMENTS were made by ECKMAN (*Journ. Amer. Med. Assoc.*, March 4th, 1922) to determine to what extent, if at all, the antiscorbutic vitamin is contained in dehydrated fruits. The experiments consisted in feeding observations on guinea-pigs. The dried fruits used were peaches, apricots, apples, pears, prunes, cherries, and loganberries. Water and alfalfa-flour mixture were given *ad libitum*, and varying amounts of the fruit were used. When scurvy symptoms were prominent and marked loss of weight occurred, the amount of fruit was increased in the effort to prevent a fatal issue of the disease. Post-mortem examinations of practically all of the animals were made, and in all cases definite evidences of scurvy were observed, such as subperiosteal haemorrhages, especially in the limbs and cheeks, evidence of intramuscular and subcutaneous haemorrhages, haemorrhagic nodules at the costochondral junctions, and enlarged and haemorrhagic suprarenals. The principal ante-mortem signs were marked loss of weight and appetite, subcutaneous haemorrhages, marked pseudo-paralysis of the limbs, and in one case (on apples) a prolapse of the rectum. From these experiments it appears evident that the only one of the dried fruits tested which contains sufficient antiscorbutic vitamin to maintain the life of a guinea-pig when fed in not too excessive quantities is the peach. Of this fruit it appears that 4 grams a day, although insufficient to prevent scurvy, delays it for three or four months. Although further trial did not bear it out, earlier experiments indicated some value in apricots and apples. Pears, prunes, loganberries, and cherries seemed to have even less value.

329. The Value of Specific Treatment in Parenchymatous Keratitis.

LANGENDORFF (*Dent. med. Woch.*, March 2nd, 1922) asks why antisyphilitic treatment is supposed to be disappointing in parenchymatous keratitis, and a study of the 165 cases treated at the Rudolf Virchow Hospital between 1907 and 1921 has led him to the conclusion that specific treatment is undoubtedly beneficial, although its action is not dramatic. He founds this opinion on the observation that the disease invariably ran a milder course in the second eye, provided specific treatment of the first eye was instituted before the disease had become manifest in the second eye. The most reliable test of the severity of a disease of the eye is to note the degree of vision left after the culmination of this disease, and, judged by this test, the value of consistent specific treatment stood out plainly. In 44 per cent. the second eye was perfectly healthy on the patient's admission to hospital. In one-fifth of these cases the second eye required no treatment; in the remaining four on the completion of treatment. The difference in the Wassermann reaction before and after treatment, whether this consisted of mercury or salvarsan or a combination of the two. But this does not discourage the author, whose belief in the benefit of specific treatment rests on the comparative immunity enjoyed by the second eye when treatment is instituted early.

320. **Meningococcal Meningitis following Septicæmia.**
KRAMER (*Nederl. Tijdschr. v. Geneesk.*, January 21st, 1922) remarks that infection with Weichselbaum's meningococcus may give rise to three different conditions—namely: (1) Infection of the mucous membrane of the nose and throat without any other symptoms; (2) infection of the meninges; (3) septicæmia. In most cases meningitis occurs so rapidly that it is difficult to determine whether it has been preceded by septicæmia, but it is much commoner for definite signs of septicæmia, such as purpura, endocarditis, pericarditis, arthritis, etc., to develop during the course of meningitis. There are some cases on record of meningococcal involvement, and several weeks' duration of meningococci after a septicæmia and give rise to meningitis. Kramer records an example of the latter condition in a youth aged 19, who, after an illness of six weeks (the septicæmic nature of which was shown by continued fever, recurrent arthritis, erythema multiforme, and purpura), developed meningitis. Recovery took place after lumbar puncture without serum.

331. **Craniotabes and Syphilitic Rickets.**
MARFAN (*Paris méd.*, December 24th, 1921) remarks that though syphilis may give rise to all forms of rickets, as a rule it produces a special clinical form which is distinguished by the following characteristics: (1) Early onset. It is either congenital or appears in the first three or four months of life. This is the most important feature, for all the others depend upon it. (2) Predominance of rachitic changes in the skull bones. Craniotabes is first observed, and later abnormal prominence of the frontal and parietal eminences. When rickets is due to another cause, especially tuberculosis and severe and persistent digestive disturbances, the skull often escapes entirely or is but little affected, and hardly ever shows any craniotabes. (3) Anaemia, which is well marked at least during the first few months of life. (4) Chronic enlargement of the spleen. The last two characteristics of syphilitic rickets tend to disappear in the course of the second year or even earlier, but the cranial stigmata persist for years and even throughout life. Rickets due to tuberculosis or digestive disturbance as a rule produces only a slight deformity, because it develops at a period of life when the skeleton is much more consolidated. Marfan emphasizes the fact that craniotabes is not due to a mere delay in ossification, as maintained by Comby, Lasègue, Wichmann, and Lasage, but is the manifestation of rickets with an early onset which in most cases is of syphilitic origin.

SURGERY.

332. **Ear Disease in Infants.**
ROBERT-LEROUX (*Presse médicale*, December 17th, 1921) draws attention to the frequency and serious consequences of otitis media in the newly born and suckling infant, and discusses the means which may be adopted to prevent ear disease. Whilst in the adult attention is drawn to the ear by the symptoms of pain, fever, and impairment of hearing, in the infant the first indication may be that the external ear is full of pus. But middle-ear disease is of such common occurrence amongst children that in every obscure illness of an infant a thorough examination of the tympanum should be carried out, and, if the appearances suggest disease, or even if they are only doubtful, paracentesis should be performed. Such grave consequences follow failure to relieve pent-up pus in the middle ear—namely, septicæmia, or meningitis, or permanent deafness—that the simple operation of paracentesis is always justified in a doubtful case. Amongst 42 infants admitted to hospital under various labels as "urgent" cases 37 were found to be suffering from unrecognized otitis media. The anatomical conditions accountable for this infection are as follows: The Eustachian tube in the newborn infant to the infant than in an adult, and leads in this stage may be full of cavity of the middle ear, which later becomes replaced by gelatinous embryonic tissue, which later becomes replaced by air. Here is an ideal breeding place for germs which entered from the throat, proved by the fact that punctures of the tympanum in early cases of ear disease in children frequently yield a sero-sanguinous fluid rich in streptococci and staphylococci. If this disease is unrecognized in its early stages it may be followed by perforation of the drum, which is a fortunate complication, for in other cases the unrelieved pus may spread to the meninges or blood stream. Such a

perforation should be examined carefully, and if necessary enlarged to allow of better drainage, which may be assisted by a filament of gauze and peroxide. The mastoid should be carefully watched, and any indication of retention of pus demands that the mastoid be opened by the 'gouge and enucleate' method. Since septic material is often sucked up into the nose with the first inspirations at birth, the author is of the opinion that as much care should be expended on the nose of a newborn infant as is devoted to its eyes. Swabbing the nose with plugs of absorbent cotton-wool until perfectly dry, then insufflation of powder containing two parts of finely powdered boric acid and one part of colloidal silver for the purpose of inducing sneezing, and finally the application of an antiseptic in the form of argyrol in glycerin, is the ritual he recommends. The author thinks that the dorsal position of repose is the most dangerous for an infant in that it favours regurgitation of mucus and milk into the Eustachian tube.

Giant Vesical Calculi.

333. CUMMER and BRUTSCH (*Journ. d'Urol.*, tome xii, No. 3), who record an illustrative case in a man aged 64, admitted to the Geneva Surgical Clinic for cystitis, remark that giant calculi—that is, calculi weighing more than 100 grams—are a rarity, as is shown by the following statistics: 4 in 300 (Freyer), 1 in 312 (Madden), 1 in 292 (Dirnse), 1 in 104 (Christovitch), although these surgeons were practising in countries where stone in the bladder is particularly frequent. Giant calculi do not present any characteristic clinical picture, the only feature common to all the cases being the absence of all symptoms until an advanced stage of their growth. In most of the cases there are no diverticula to explain this absence of symptoms. Some of the calculi are composed entirely of uric acid, while others consist exclusively of ammonio-magnesium phosphate, indicating a long-standing vesical infection. The etiology is uncertain. Although many of these calculi have been observed in countries where bilharzia is present, others like the writers' case have occurred in countries where stone in the bladder is comparatively rare. The prognosis, which is grave, depends chiefly on the existence of infection and the condition of the renal and vesical functions. In the writers' case three stones, weighing in all 585 grams, were removed from the bladder, the largest being contained in the diverticulum, and the other two being free in the bladder. All three were composed entirely of ammonio-magnesium phosphate. The renal function was not affected. Removal of the stones improved the patient's general condition, but gave rise to complete retention owing to the situation and size of the diverticulum.

Treatment of Sciatica.

334. BARRÉ and GUNSETT (*Journ. de radiol. et d'électrol.*, Norember, 1921) have treated by x rays 20 cases of sciatica in which the symptoms were due to radiculitis caused by vertebral arthritis, as shown by x-ray examination; 12 of the cases were cured, 5 were improved, and 3 only derived no relief. The forms which were most susceptible to treatment by x rays were those in which pain constituted the most prominent sign. The patients hardly ever showed any amyotrophy or changes in the reflexes. Radiculitis of meningeal origin, such as that caused by syphilitic meningitis, did not appear to be definitely affected by the treatment. In cases in which radicular pain was associated with pyramidal disturbance x rays generally had no effect on the latter. The writers found that the chances of success were not decidedly diminished by the fact that the radicular pain was of old standing, although recent cases were more susceptible to treatment. As a rule small doses repeated once a week were sufficient to produce a cure. In some cases no improvement occurred, although no explanation of the failure could be given.

325. **The Dangers of Diagnostic Pneumo-Peritoneum.**
JOSEFSON (*Hygiea*, January 16th, 1922) inveighs against the practice of injecting gas into the peritoneal cavity as a supplement to diagnosis by the x rays. He has induced a pneumoperitoneum in sixteen cases, in none of which did it help the patient appreciably, whereas it injured two and caused discomfort to six. Compared with an exploratory laparotomy, this device is very uninformative, and it entails grave risks of injury to the intestines, air embolism and other serious accidents. One of the author's patients, whose heart was weak, died soon after the injection of gas, and he refers to two fatalities recorded in 1921, in one of which death was due to air embolism. Surgical emphysema is another complication, and there is no absolute guarantee that the intestines or stomach do not get perforated. The benefits accruing being very doubtful, the author considers that the drawbacks to this procedure should lead to its being almost completely discarded.

336. Tumours of the Temporal Lobe.

ACCORDING to COSTANTINI (*Il Policlinico*, Sez. Med., November 19th, 1921), who records two cases, general symptoms are present in tumours of the temporal lobe and appear early. They include psychical disturbances of various kinds. Ingazzini in his cases observed dullness, apathy, disorientation, or irritability and illusions. Knapp has shown that a syndrome resembling Korsakow's psychosis is frequent, consisting in diminution of attention, amnesia, incoherence, disorientation in space and time, and euphoria. Localizing symptoms are frequent and of different kinds. The most important (in tumours of the left temporal lobe) are disturbances of speech and special sense, including simple paraphasia, ordinary sensory aphasia, transcortical acoustic aphasia, and amnesic aphasia. The focal symptoms often concern special groups by means of which the special area affected by the growth may be determined. None of the local symptoms, however, can be called constant. They may or may not be totally absent, so that it is impossible to determine a special zone affected by the tumour.

337. Peripheral Iridotomy in Glaucoma.

GIFFORD (*Amer. Journ. Ophthalmol.*, December, 1921) points out the value of peripheral iridotomy (Curran) in the treatment of chronic, and of some cases of acute, glaucoma, on the theory that the increase of tension is caused by a too close contact of the lens to the posterior surface of the iris and consequent interference with the flow from the posterior to the anterior chamber. A sharp Knapp's knife needle is passed through the corneo-scleral junction, and the iris transversely punctured and counter-punctured to make a hole 1 mm. in size. From a personal experience in 30 cases of chronic glaucoma the operation in nearly every instance gave relief for several months. The operation is so simple and free from strain or danger that it can be performed several times if necessary, or to reduce the danger of the more serious iridectomy should that eventually be needed. Sufficient time has not yet elapsed to prove to what extent the cure is permanent, though in many cases the relief obtained is probably lasting.

338. Tuberculosis of the First Metatarsal in the Child.

ACCORDING to SORREL and BONGQUIER (*Paris méd.*, November 19th, 1921), all writers are agreed as to the frequency of tuberculosis of the first metatarsal in the child. Baillet found that of 82 cases in which the metatarsus was affected, the first metatarsal was implicated in 45. Royal Whitman stated that the first metatarsal alone was involved as frequently as the four others together. Out of 30 children under the care of Sorrel and Bongquier at the Berck Hospital for metatarsal tuberculosis, the first metatarsal was affected in 18. Two explanations have been offered for the frequency with which the first metatarsal is attacked by tuberculosis. Kirinsson attributes it to this bone being the support of the plantar arch, while Baillet considers that it is due to the first metatarsal, more than any other long bone in the hands and feet, possessing the largest amount of spongy tissue, which offers a favourable soil for the development of the tubercle bacillus. Sorrel and Bongquier describe three forms of tuberculosis of the first metatarsal, according as the shaft alone or the anterior or posterior extremity is affected. In the first, or diaphyseal form, if both the extremities are intact, conservative treatment should be adopted. In disease of the anterior extremity the bone must be amputated, but always in front of the diaphyso-epiphyseal cartilage. The great toe should also be removed at the same time. In disease of the posterior extremity not only is amputation necessary, but the metatarsal must be disarticulated, together with the great toe.

339. Treatment of Cold Abscesses.

OTT (*Il Policlinico*, Sez. Prat., January 30th, 1922) has treated about 30 cold abscesses in various situations and a few cases of suppurative adenitis in the following way: After the abscess had been opened in the usual manner and the pus aspirated with a syringe, the cavity was washed out with a solution of hypertonic saline until the returning fluid was clear, and a certain amount of the same solution was injected into the cavity according to the size of the abscess. This operation was repeated at intervals of four or five days, until the abscess was filled with a clear fluid, which, on microscopic examination, showed only one or two leucocytes in a field—a result which, in the most favourable cases, was obtained after the cavity had been washed out four or five times. Healing took place in twenty to sixty days according to the size of the abscess. The hypertonic solution used consisted, according to Wright's formula, of 5 grams of sodium chloride and 50 c.c. of sodium citrate to 100 c.c. of distilled water.

OBSTETRICS AND GYNAECOLOGY.

340. Haemolytic Streptococci and Obstetric Prognosis.

KIRSTEIN (*Arch. f. Gynäk.*, 1922, cxv, 2) investigated the relation between the incidence of post-partum infections and complications and the presence of haemolytic organisms in cultures made from the vagina during and after labour. He classified cases of puerperal fever in respect of three increasing degrees of severity, and found that a greatly increased percentage of "class 3" (the most serious cases) showed themselves in those in whom cultures gave *Streptococcus haemolyticus*. Severe complications, such as adnexal inflammation, were more frequent in the cases associated with haemolytic organisms. One in ten only of the class 3 patients were not infected with these cocci. Obstetric operations *intra partum* were less well tolerated by the patients infected with haemolytic organisms, twice as many in these as in other patients showing subsequent pyrexia. Of fifty-three patients in whom cultures at parturition showed haemolytic streptococci 92 per cent. subsequently became febrile. The writer concludes that in cases known to be infected with haemolytic streptococci it is inadvisable to perform primary suture of perineal tears, and that prophylactic drainage of the uterus by means of a tube introduced *post partum* may be usefully undertaken.

341. Induction of Labour versus Caesarean Section.

SHERWIN (*Med. Journ. of Australia*, January 21st, 1922) considers that induction of labour is preferable to Caesarean section on account of its greater simplicity and more satisfactory results to both mother and child. Kransse's method, by the insertion of two or more biongles between the membranes and the uterine wall, is advocated as better than dilatation of the cervix. The principal indications for induction are contracted pelvis, toxic albuminuria, ante-partum haemorrhage, cardiac or constitutional disease, or the history of a large child at previous confinements. In contracted pelvis induction of labour is indicated when, after careful weekly examinations, it is found that the foetal head will just not enter the brim, and in a series of 72 cases so treated there was no maternal death. In central placenta praevia in an uninfected primipara Caesarean section is advised, but in a multipara induction of labour is best. In eclampsia rigid observations upon primiparae should be made from the twenty-fourth week onwards in order that induction may be induced in the pre-eclamptic stage. Comparison of statistics of two hospitals, in one of which the performance of Caesarean section averaged 7 per cent., while in the other it averaged 16 per cent., showed that the maternal death rate in the former was 2.6 per cent., while in the latter it was 21 per cent., or nearly ten times greater, the infant mortality being 6 per cent. as against 12 per cent.—exactly double.

342. Treatment of Chronic Adnexal Inflammation.

PROBSTER (*Zentralbl. f. Gynäk.*, February 18th, 1922), from a study of 101 cases of radical and of 28 cases of conservative operation for chronic adnexal disease, comes to the following conclusions: Resort should be had to operation only in cases in which the symptoms are of some years' duration with intermittent exacerbations and in which the patient is rendered incapable of carrying out her work; in patients, however, whose social position does not permit of a prolonged course of non-operative treatment, it may be advisable to operate earlier. Operations should not be performed until several months have elapsed since an inflammatory attack. As a rule an operation is preferable which removes the uterus and the adnexa of both sides; conservative operations find their place chiefly in cases following puerperal infection. The writer records 88 per cent. of cases of complete cure and 95 per cent. of return of vocational capacity, with 5 per cent. mortality, in 101 cases coming to radical operation. In spite of careful selection of cases the results of conservative operations were less satisfactory. Morbid symptoms due to the induced menopause were noticeable, chiefly in slightly psychopathic subjects, but were never of such intensity as seriously to impair the therapeutic results.

343. Protein Therapy in Pregnancy Toxaemias.

LEVI (*Annali di Ostetricia e Ginecologia*, February 28th, 1922) treated three patients, suffering during the early months of pregnancy from intractable vomiting, by injections into the gluteal muscles of 5 to 10 c.c. of sterilized milk given at intervals of one to three days; in each case a marked improvement followed, and it became safe to allow the gestation to continue to term. Two other patients were also found to respond to milk injections; in their cases, however—characterized respectively by sensorimotor paresis of the hands and by persistent hypersalivation—the antotoxic nature

of the malady was less well established. Levi, in common with other writers, has seen in cases of pregnancy, albuminuria, eclampsia, hyperemesis, and chorea good results follow parenteral injections of foreign proteins such as horse, goat, or human serum, or of dehydrated blood. These, he thinks, whether possessing or not a specific action, appear in some cases more efficacious than milk injections; but human serum is not readily obtained, and the injection of animal serums is not without noxious effects both on mother and foetus. In Levi's five cases the injections were followed by scarcely any febrile reaction; this, he remarks, does not support the contention of those who have ascribed the effects of protein therapy to stimulation of the heat-regulating centre. It is suggested that if found constant this lack of febrile reaction after an injection of milk might be of assistance in differential diagnosis of adnexal inflammatory conditions from extrauterine pregnancy.

344. Heliotherapy in Gynaecological Practice.

COLOMBINO and MOZZETTI-MONTERUMICI (*Annali di Ostetricia e Ginecologia*, February 28th, 1922) contribute a preliminary report of the treatment of gynaecological disorders by ultraviolet radiation, applied by means of a Landeker's lamp, which is susceptible of application to the portio vaginalis or to any of the vaginal fornices. Among the cases treated were 10 of exudative adnexal inflammations, of septic or gonococcal origin, in the apyrexial stage. Of these, 5 showed after four to ten applications, given in the course of one to three weeks, speedy disappearance of objective and subjective morbid signs: three patients reported symptomatic improvement, but showed few objective alterations, and the remaining two—old-standing and probably cicatricial cases—were unaffected. Applied in cases of parametritis following parturition or abortion, the treatment was very successful in one of four cases. Favourable results were obtained in the treatment of chronic cervicitis and leucorrhoea. In the case of a faecal fistula following laparotomy for tuberculous adnexal disease and of a large perineal ulceration following operation for anal fistula, proved to be of tuberculous origin, artificial heliotherapy was rapidly efficacious. Given on successive days for periods of thirty minutes, it was not followed by unpleasant reactions, even in patients suffering from subacute or relapsing inflammatory conditions.

PATHOLOGY.

345. Inoculation of Human Malignant Tumours in Mice.

KEYSSER (*Arch. f. Klin. Chir.*, November, 1921) reports that he has successfully inoculated malignant tumours from human sources into the mouse. The essential points of the technique employed are that the activity of the tumour cells must previously have been intensified by radium treatment insufficiently strong to destroy them, and that the animal must have been sensitized by antecedent injections of tumour cells derived from other species. Injections of an emulsion of tumour cells diluted to 1 in 30 or 1 in 35 are made into various organs; the tumour formation, which takes place by no means constantly, is manifested after an incubation period of seven to twelve months, as contrasted with one of seven or eight weeks in the case of spontaneous mouse tumours. The grafts have positive results in about 2 per cent. of cases, both as regards human and mouse tumours; the proportion is increased after the fourth passage to 30 per cent. in the case of the human and 100 per cent. in the case of the mouse tumour. In his later report Keysser has had positive results from injection of cells from a sarcoma of the testicle refractory to radium treatment, a carcinoma of the penis, a branchial carcinoma, and a cylindrical-celled carcinoma. In one of the animals into which a fourth passage of the sarcoma had been made a squamous-celled carcinoma was produced. The experimental tumours of the mice were examined by Aschoff and were pronounced to be true tumours of which the cells showed the characters not of human cells but of the corresponding mouse tissue. This is susceptible of three explanations, of which the second appears the least probable: (1) the inoculated tissue by chemical irritation provokes pathological cell reproduction; (2) the cells of the transplanted tumour tissue become modified by a process of adaptation so as to resemble those of the neighbouring tissue; (3) an unknown specific micro-organism is inoculated.

Yaws and Syphilis.

346. MOSS and BIGELOW (*Johns Hopkins Hosp. Bull.*, February, 1922), in an excellent and well-illustrated paper, analyse 1,046 cases of yaws which they observed in the Dominican Republic. They are strongly opposed to the theory that

yaws and syphilis are essentially the same disease. They point out that the primary lesion in syphilis is in the majority of cases located on the genitalia, whereas in yaws only 1 per cent. have this location. The primary lesion is larger and rougher than the syphilitic chancre, even when this is extragenital, and it is never indurated. In no case was there any evidence or history of hereditary transmission. In 25 per cent. of the cases the infection took place before the fifth year of life. With regard to the secondary stage of the disease, the granulomata of yaws present a monotonous resemblance to each other; there is none of the remarkable pleomorphism of the secondary lesions of syphilis. None of the yaws cases showed macular skin rash, mucous patches, or alopecia. In the tertiary stage of the disease the absence of visceral involvement, especially of the heart, blood vessels, liver, and kidneys, is in strong contrast with the frequency of their involvement in syphilis. Moreover, in a series of over 1,000 cases in which the average duration was twenty years, none showed any evidence of central nervous system involvement.

347. The Diameter of Human Red Blood Corpuscles at Different Ages.

IN the absence of any definite knowledge on the size of the red blood cells in man considered in relation to the age of the individual, SARAGEA (*C. R. Soc. Biologie*, February 11th, 1922) has made an examination of the corpuscles of healthy people who varied in age between 1 day and 90 years. The average diameter obtained for adult men and women between 30 and 50 years old was 7.55μ , a figure which closely corresponds to that found by Malassez—namely, one of about 7.6μ . At birth, however, the red cells are considerably larger, measuring 8.62μ across. From this period they gradually decline to the age of 18 months, when the diameter is 7.13μ . Somewhere about this figure is retained till puberty is reached, when a sudden increase to 7.68μ is noticed. After remaining more or less constant during the period of adult life, they increase somewhat at the age of 60 and maintain an elevated figure throughout old age. At present the significance of such alterations is unknown. In certain pathological conditions, such as pernicious anaemia, post-haemorrhagic anaemia, in certain types of jaundice, and in chronic congenital cyanosis, the diameter of the red cells is increased; but here again we are ignorant of the interpretation to be placed upon the facts.

348. The Anti-anaphylactic Action of Lipoids.

DUPREZ (*C. R. Soc. Biologie*, February 4th, 1922) shows how it is possible to prevent the symptoms of acute anaphylactic shock in the guinea-pig by means of the previous injection of a lipoidal emulsion. The particular lipoids used are prepared by making an alcoholic extract of a calf's heart which has been treated preliminarily with acetone. After evaporating the extract to dryness, the residue is dissolved in saline. The guinea-pigs are sensitized by the subcutaneous injection of 2 c.c.m. of horse serum. Three weeks later a determination is made of the minimal lethal dose of horse serum given intravenously. If now, one hour before the dechaining dose is given, an injection of 2 c.c.m. of the lipoidal emulsion be administered intravenously, all symptoms of shock are prevented. Not only is this method successful in protecting against horse serum anaphylaxis, but it appears to be equally efficacious in warding off the symptoms produced by other substances normally capable of giving rise to shock in the guinea-pig, such as serum treated with agar or a suspension of agar in physiological saline. The mechanism of this effect has not yet been worked out.

349. Distribution of the Nitrogen in the Protein of Chicken Sarcoma.

AN attempt has been made by FURUHATA (*Gann, the Japanese Journal of Cancer Research*, December, 1921) to solve the question concerning the nature of the cancer cell along chemical lines. For this purpose an investigation of the Rous chicken sarcoma was carried out and the results compared with those obtained by an analysis of the normal tissues. Van Slyke's method of nitrogen determination was employed throughout. Figures for the total nitrogen, and for the ammonia-N, melanin-N, cystine-N, arginine-N, histidine-N, lysine-N, and for the total mono-amino-N are furnished in the text. Comparing the nitrogen distribution in the sarcoma tissue with that found in healthy muscle and liver, he fails to note any marked difference, though the amount of melanin and diamino-acid nitrogen appears to be slightly higher in the tumour tissue, probably owing to the highly cellular nature of the growth. This inability to discover any definite alteration in the nitrogen distribution of sarcoma cells leads him to suggest that the constitution of normal and of tumour cells is the same.

BISHOP'S SOLUBLE ASPIRIN IN TABLETS Registered Name LITMOPYRINE

Each Tablet contains 5 grains of Lithium Acetyl Salicylate.

PERFECTLY SOLUBLE IN WATER.

LITMOPYRINE TABLETS DO NOT UPSET THE STOMACH.

ANTIPYRETIC, ANALGESIC, DIAPHORETIC.

INDICATIONS:—Muscular and Articular Rheumatism, Polyarthrititis, Sciatica, Gout, Lumbago, Influenza, and all Feverish Conditions, Colds, Catarrhs, Bronchitis, Headaches and Neuralgia.

BOTTLES:—Containing 100 Tablets—4/6 post free. Also supplied in powder form and as a Granular Effervescent. Samples and Descriptive Literature sent free to Medical Men by the Sole Manufacturers of Litmopyrine.

ALFRED BISHOP, LIMITED, Manufacturing Chemists, 48, Spelman St., LONDON, E.1.

THE FRENCH NATURAL MINERAL WATER

VICHY-CELESTINS

Property of the FRENCH STATE.

FOR DISORDERS OF
THE LIVER AND KIDNEYS

USE 2 GALLONS

instead of 3 and get the same mileage.

It almost sounds too good to be true, but it is actually being done every day by hundreds of motorists—some are saving even more.

The "WHALLEY" Air Valve has been proved for the last 9 years; it will save from 25 per cent. to 50 per cent. of motor spirit.

The "Whalley" Air Valve is welcomed by the motorist seeking

engineering proposition.

You can fit it yourself, as no drilling is required, and it does not spoil the appearance of any part of your car.

The "WHALLEY" Air Valve enables you to obtain perfect carburation at all speeds. This means engine efficiency and a consequent saving of spirit.

Specially designed Models for Cars as follows:—
Sunbeam 6-cylinder (twin carburetter), Armstrong-Siddeley (twin carburetter), Standard, 8-cylinder, Overland, Ford, Dodge 8-cylinder, and G. H. Cycle Car.

Backed by the House of Hollingdrake—engineers of a century's standing.

All Popular Models 45/- each. Postage 1/-.
Write to the Manufacturers for free booklet.

Intestinal Disinfection

ALIMENTARY TOXÆMIAS

No. 2

IN our last advertisement the subject of Alimentary Toxæmia was briefly discussed and Intestinal disinfection by means of Kerol Capsules was held to be the first line of treatment.

The reason for this may be stated as follows:—None of the ordinary so-called Intestinal antiseptics, such as Salol and Beta Naphthol are found experimentally to exert any disinfection of the contents of the bowel.

On the other hand, the high boiling hydroxy compounds of the coal tar series are potent germicides, and being unabsorbed are non-toxic. They can therefore be administered freely without harm and are found to prevent the multiplication of the toxæmic intestinal bacteria and to considerably reduce them.

The active principle of Kerol is a complex mixture of these compounds. The administration of two 3 minim Capsules, thrice daily after meals has been repeatedly shown to reduce the colic content of the stools of individuals taking them by 99% (vide THE MEDICAL PRESS AND CIRCULAR, January 14th, 1914).

For intestinal disinfection, use Kerol Capsules (keratin-coated); they contain 3 minims of Kerol. 1 to 3 Capsules may be given 3 or 4 times a day after meals.

KEROL CAPSULES

Please send for literature and Samples, which will be sent free to any member of the Medical Profession.

TOPICAL ELECTRO-MEDICAL NEWS

JUDGE: Gentlemen of the Jury, what you have to consider is did Dr. Obsolete exercise proper and reasonable care in his treatment of this case.

There is evidence that plaintiff suggested the use of X-rays which alone could show exactly the state of the injury, and I should have thought that for his own sake as well as for his patients sake he would have taken a radiogram seeing the process is now so simple that any one of you gentlemen could learn what is necessary in about an hour. But the fact remains that he did not do so, and I therefore decide that he was guilty of negligence and did not exercise proper care on behalf of his patient. It is for you to say what damages the plaintiff is entitled.

NOTE WHAT THE LEADING RADIOLOGISTS ARE SAYING.

REVOLUTION IN RADIOGRAPHY

Reduced Initial Cost
Reduced Running Cost
Reduced Exposures
Reduced Risk of Injury
Reduced Plate Cost
Reduced Tube Cost
Reduced Skill required
Perfect Radiograms

AND THEN CONSIDER WHY DID THE AMERICAN ARMY

ADOPT
this system for their Radio-
logical Work in the

HIGHEST AWARD LAST INTERNATIONAL MEDICAL CONGRESS.

A British Medical Association Lecture ON MINOR DISPLACEMENTS OF THE UTERUS AS A CAUSE OF DISABILITY IN WOMEN.

BY

JOHN S. FAIRBAIRN, M.A., M.B., F.R.C.P.,

OBSTETRIC PHYSICIAN, ST. THOMAS'S HOSPITAL; LECTURER ON MIDWIFERY
AND DISEASES OF WOMEN, ST. THOMAS'S HOSPITAL MEDICAL SCHOOL.

IN disorders of the female pelvic organs, as in general medicine, the cause is readily determined if there is an obvious gross lesion, such as an inflammatory mass or new growth, but difficulty arises when evidence of localization is uncertain and physical signs absent or trifling. The problem is then one of interpreting the meaning and estimating the importance of some minor deviation from the average, and deciding whether it falls within the limits of normal anatomical variation or can be held responsible for the patient's symptoms.

There is a personal factor in the interpretation of symptoms with little in the way of physical signs, and among gynaecologists, as among physicians and surgeons, there will be many individual differences of opinion. There are two extremes—the mechanical school and the psychical school—the former will find for all disorders of function, particularly in the abdomen and pelvis, some kink or twist or displacement which satisfies them as the cause of the trouble, while the latter will ascribe the chief part in the production of the patient's disability to some subconscious mental process or repressed or unexpressed sexual desire. No doubt as time goes on the true mean between these extremes will be reached, but meanwhile the bent of mind of the individual observer will largely determine on which of these factors the stress will be laid.

I propose to discuss this afternoon the minor displacements of the uterus—that is, excluding obvious descent—and to attempt to estimate their importance as a cause of disability in women.

Looked at from the historical aspect, it will be seen that uterine displacements came into special prominence in the mid-Victorian era—a time when it was exceedingly difficult for a woman to have her uterus just as it ought to be, as it was thought that its proper position should be in the axis of the pelvic inlet; if it was in front of that position it was looked upon as anteverted or anteфлекed, and if behind as retroverted or retroфлекed. Now all displacements have died a natural death except the backward one, which, as the last survivor, has inherited all the wealth of the family in the way of symptoms. An index of the change in attitude towards these uterine displacements can be obtained by glancing at the edition of *A System of Gynaecology*, edited by Allbutt and Playfair, published in 1896, and its successor, *A New System of Gynaecology*, by Edon and Lockyer, published in 1917. In the 1896 edition Professor A. R. Simpson of Edinburgh describes in detail uterine displacements, forward, and backward, and sideward, so that we find mentioned even dextro- and sinistro-versions and flexions, though with an obvious mental reservation as to whether the anterior displacements ought not to be eliminated altogether from the category of uterine disorders. In the *New System of Gynaecology* of 1917 the displacements have disappeared entirely, except the backward, which is the only one considered. The author of the article, Professor Chipman of Montreal, summarizes his views as follows:

"All these signs and symptoms may be found with no retroversion whatever, for these may result from altogether different causes. Their presence is in no sense pathognomonic of this, or of any uterine displacement, and so the displacement may be but a coincidence and possess no etiological significance whatever."

"In actual practice it is fair, I think, to regard retroversion of the uterus unaccompanied by prolapse as of no importance save only as a certain predisposition towards prolapse. It is specially wise in these cases to treat the symptoms of which the patient may complain upon general and broad lines, rather to avoid than encourage local treatment, and only if the general treatment fail—and this in my experience will rarely be the case—is one to attend in any way to the 'backward displacement.'"

What was not appreciated by the older gynaecologists was that the uterus is an organ which is liable to great variation in position as the result of changes in the surrounding viscera and in the intra-abdominal pressure, that its blood supply and attachments are arranged to permit of its being

either a pelvic or abdominal organ, and that it is perfectly comfortable with its fundus on the pelvic floor or just under the diaphragm. It is now generally recognized that its position, *qua* position, is of no clinical importance, and that what we have to look for is the cause of the unusual position and consider whether that cause is one requiring treatment. The most common cause of retroversion is prolapse of the pelvic floor, of which the uterus forms part; usually retroversion with descent is the first indication of prolapse. Infectious, including subinvolution, are a cause of simple and fixed retroversion; growths, such as ovarian cysts and uterine fibroids, are another cause of displacement of the uterus; and a rarer cause is maldevelopment, occasionally seen in nulliparae.

Retroversion is very common in multiparae, and is occasionally met with in nulliparae when examined for dysmenorrhoea or sterility, or because of symptoms which might have a pelvic origin. In the latter the backward position is classed as a congenital peculiarity, but until figures can be obtained by investigation of large numbers of healthy girls and women so as to obtain an idea of the frequency of the retroverted, as compared with the anteverted, position, it is impossible to dogmatize on its clinical importance. It may tend to sterility and abortion; though occasionally found when dilating for dysmenorrhoea, it is very much rarer than the usual anteverted and anteфлекed position, so that, until statistics as to the percentage of dysmenorrhoeics with backward and with forward position of the uterus are obtained and compared with the incidence of these positions in nulliparae generally, it is impossible to make positive statements. Some of these retroverted and retroфлекed uteri in virgins with dysmenorrhoea are small and infantile and associated with scanty menstruation, just as is seen with the small anteverted and anteфлекed uterus, and thus it would appear that incomplete development, and not the forward or backward position, is the determining factor in the production of dysmenorrhoea.

In parous women the uterus is often found to be retroverted because pregnancy and labour and lying-in are the factors which tend to produce this position; in multiparae with a relaxed abdominal wall and enteroptosis the backward is almost as common as the forward position. The softening of the uterus and its attachments and the stretching of ligaments and muscles during pregnancy, the further stretching and laceration during labour, the dorsal position, overdistension of the bladder, the assumption of the erect position and the resumption of work before involution is complete, are all predisposing factors.

It may be worth while to consider in detail the symptoms commonly ascribed to the backward displacement.

Backache, a symptom of nearly every pelvic disturbance, is probably more common among women with retroversion than anteversion because of the frequency with which abdominal wall and pelvic floor weakness, enteroptosis, subinvolution, and other enlargements of the uterus are associated with a backward position. As backache is largely a fatigue effect and the symptom *par excellence* of the tired woman possibly this fatigue may appear earlier when the uterus is back than when forward, and, if so, probably because of the associated conditions rather than the mere uterine position.

Bearing down is a sensation so closely associated with weakness of the sustentacular structures that its occurrence with retroversion should at once suggest that pelvic floor weakness is the cause, and that the position of the uterus represents an early stage of prolapse. With a lowered resistance to disagreeable sensations, other varieties of aching and pain will occur as an early result of fatigue, and are commonly attributed to retroversion, if it happens to be present.

Menorrhagia is another symptom said to be more common among women with retroverted than with anteverted uteri. There is an armchair hypothesis, generally swallowed without much hesitation, that pelvic pain and aching, menorrhagia, and leucorrhoea are due to a uterine congestion from an obstruction to the venous return. Beyond the fact that such theory forms a reasonable explanation for the above symptoms, and that these symptoms are sometimes cured by the uterus being supported in anteversion, I know of no observations in support of this hypothetical passive congestion and many points which it leaves unexplained. This menorrhagia is quite haphazard in its occurrence, and the majority of women with retroversion do not suffer from it; there is no naked-eye or other evidence of passive congestion observed when operating, by abdomen or vagina, in cases in which the uterus is retroverted; the remote

of a chronic venous congestion are not retroverted uteri; on the other hand, the hyperplasia of the cervix in prolapse is the effect of a passive congestion, which, however, does not produce menorrhagia. Menorrhagia from this presumed congestion is absent from, and is not characteristic of, the uterus pushed backwards by an ovarian cyst or other tumour in front of it, a condition in which obstruction to the venous return would appear more likely than in a simple retroversion.

Leucorrhoea is another symptom which it is not possible to say is relatively more common with retroverted than anteverted uteri; it is certainly almost invariable with retroversion and subinvolution, and with laceration and infection of the cervix. There is no proof that the retroverted position, apart from laceration and infection, increases the uterine secretions.

Dysmenorrhoea of the so-called congestive type, explained also on the presumption of a venous congestion, is a rare accompaniment of simple retroversion, and, when present, is commonly due to some complicating infective process.

Disturbances of micturition are not caused by a simple retroversion. Retention may result from the incarceration in the pelvis of a retroverted uterus, enlarged by pregnancy or fibroids to a size big enough to cause impaction; incontinence on coughing or straining may accompany retroversion with trifling pelvic floor descent; frequency does not result from a simple retroversion.

Pressure on the rectum and tenesmus are occasionally complained of, and constipation is sometimes attributed to the two-ounce uterus leaning against the rectum. If the index finger is passed into the bowel and the finger-tip merely bent forwards against the fundus felt through the anterior rectal wall, it will suffice to raise the uterus from the bowel; it is difficult, therefore, to imagine how the progress of a faecal mass weighing much more than two ounces and propelled by peristalsis would be hindered. Haemorrhoids have also been attributed to the uterus lying back and pressing on the haemorrhoidal veins, and it cannot be denied that constipation and haemorrhoids are common in women with retroversion, as they are in women without it.

Dyspareunia is sometimes present with the uterus retroverted as it is with the uterus anteverted. It is probably due to prolapsed ovaries or to accompanying inflammation and not to the uterine position itself.

General disturbances—headache, sickness, indigestion, and abdominal pain—have all been included as counts in the indictment of the backward displacement, but without any justification whatsoever, owing to too much concentration on the mechanical factor and entirely overlooking the question of fatigue of mind and body and what it may produce. So much loose thinking has been associated with the subject of "displacements" that statements begging the whole question are frequently made, and quite seriously, in medical papers and in discussions at societies—as, for example, that "retroversion requires treatment when it causes symptoms." On inquiry these symptoms will be found to vary with the fancy of the individual, and may be widespread enough to include uterine headaches and indigestion and perhaps even a uterine cough.

If a somewhat similar reasoning to that of the postulates for proving the causative bacterial agent in an infective disease were attempted it would fail to show any connexion between retroversion and the symptoms attributed to it. First, because there is no symptom-complex peculiar to retroversion; second, because such symptoms as are ascribed to the retroversion do not occur invariably, but only occasionally; and finally, because changing the position to an anteversion does not necessarily do away with the symptoms ascribed to the displacement. I once tried to keep a record for the instruction of my students of those women coming to the gynaecological out-patient department with simple retroversion without symptoms, of those with the traditional symptoms and no retroversion, and of those with the retroversion and no symptoms. Unfortunately my figures were destroyed in a spring cleaning epidemic, and all I can remember is that the largest group was that of women with the supposed symptoms but without retroversion. Statistics from a gynaecological department are, however, of little value, as the routine examination of women without pelvic trouble is necessary to a knowledge of the frequency of retroversion without symptoms. Figures are given, varying between 15 and 30 per cent., of the proportion of women in whom the uterus is deviated backward, and attempts have been made to estimate the proportion in which the retro-

deviation caused disability, but naturally are valueless because they represent merely the personal view of the observer.

Individual opinion can be eliminated, however, by noting the gradual disappearance of "displacements" from the time of their vogue and predominance in gynaecology—a time aptly summarized in Clifford Allbutt's remark that "the uterus could justly complain that it was always being impaled on a stem or perched on a twig"—to the present day, when the retro-deviations alone obtain a grudging and hesitating adherence from writers in textbooks and treatises. The reason they have survived so long is twofold: first, retroversion is present with other pelvic conditions causing disability, in which the position of the uterus is often the most striking feature on examination; and secondly, that due importance has not yet been given to the psychical factor and fatigue by those who cannot look beyond anatomical variations. It may be thought that if retroversion is part of pelvic floor prolapse or subinvolution it matters little if the woman's disability is ascribed to the position of the uterus, but further consideration will show that the point is important.

Those who have been brought up on and have accepted the displacement doctrine will consider retroversion as capable of explaining symptoms it cannot cause, and will be satisfied with it as an explanation of acute pelvic pain, uterine haemorrhage, intestinal stasis, and even partial obstruction, and look no farther for a cause. A retroverted uterus may readily be mistaken for a small swelling adherent to the back of the uterus, and I have known of a tubal gestation, an inflammatory swelling in the pouch of Douglas, and a rectal carcinoma being taken for a retroverted uterus because of the idea that this position of the uterus could be responsible for the patient's symptoms. Not only are errors in diagnosis made more likely but wrong treatment follows if attention is directed solely to the position of the uterus. The displacement myth has produced far more invalidism and inefficiency in women than any good it has ever done. The knowledge that her womb is "misplaced" or "twisted" is a source of mental distress to the unfortunate woman who is treated for it; the wearing of a pessary and its frequent changing concentrates her attention on her pelvic organs, and she becomes convinced of her uterine weakness, which must always be considered and prevents her doing what others do. Thus is the pelvic neurasthenic manufactured, particularly among single women.

I would suggest that we follow Sir Thomas Browne's dictum that "knowledge is made by oblivion, and to purchase a clear and warrentable body of truth, we must forget and part with much we know," and I would urge that the time has come to let the backward positions of the uterus go the way of the other displacements.

In child-bearing women many of you know from your own experience that backache and bearing down are relieved by replacement of the uterus and a pessary, because, as already explained, the symptoms are caused by strain on the supporting structures. In virgins the problem is quite different, and I would lay it down as a rule that in their case pessary treatment should never be adopted; the cases in which it might be justifiable are too exceptional to affect the general applicability of the rule. In nulliparous married women temporary pessary treatment may be tried for sterility and repeated miscarriages.

In the parous woman simple retroversion is often found with an unusually mobile uterus and ptosis of the contents of the abdomen and laxity of the wall. With general enteroptosis the backward position is more common than the forward, and must be looked on as merely a fraction of the general relaxation; it would therefore show a wrong perspective of the case to concentrate solely on the uterus to the neglect of the general abdominal condition. In many cases there is also weakness and descent of the pelvic floor. The bulky subinvolved and retroverted uterus following labour is to be treated as primarily subinvolution and chronic infection, but, as will be seen later, benefit may come from its being supported, as subinvolution affects its ligamentary attachments as well.

The cases which the practitioner treats with success as cases of retroversion are almost entirely cases of slight pelvic floor injury and subinvolution, often complicated by overwork and overstrain with fatigue symptoms. The treatment of such cases is worth detailed consideration, as success largely depends on general management as well as relieving the pelvic condition.

The preventive treatment is clearly good midwifery,

avoiding laceration and infection, and a physiological management of the puerperium. During the lying-in time measures directed towards the promotion of normal and complete involution should be adopted. The patient should be encouraged to sit up and move about in bed. The hinder, which restricts the movements of the abdominal muscles, should be discarded as soon as possible, certainly within a week, and massage and breathing exercises begun as soon as the free lochia discharge has lessened and the patient's general condition allows. When the fundus uteri has sunk down so that it is only just palpable in the abdomen, the woman should be encouraged to assume the knee-elbow position for short intervals and afterwards to lie prone for a time. While in the knee-elbow position a good exercise is to make her contract her levator ani muscles by the action of "squeezing up as if to hold a motion." In this position the strain on the pelvic floor is at its minimum, and the muscles therefore work at an advantage. Another exercise for restoring the efficiency of the levator muscles may be carried out with the patient on her back by combining their contraction with that of the adductors of the thigh. The nurse may be instructed to resist adduction by placing her hands on the inside of the knee while the patient tries to bring her knees together, the resistance being slight at first and increasing as time goes on. Indeed, all muscular exercises, particularly of the abdominal, flank, back, and thigh muscles, are valuable by improving the circulation and physical condition. Breast feeding, in addition to its importance to the infant, should be encouraged for its effect in aiding involution. Though the lying-in mother requires two, or if possible three, weeks of a rest cure after the strain of pregnancy and labour, and as a preparation for the nursing and care of her infant, that time should not be one in which her muscles are allowed to become soft and flabby, so that they are incapable of performing their functions when she gets up, and nothing is so valuable as resisted muscular movements. By aiding the recovery of the abdominal and pelvic musculature and keeping up the general physical condition whilst giving the mother rest and relief from household duties and strains much can be done to lessen the frequency of retroversion and descent of the uterus, with the backache, forcing down sensations, and early fatigue that detract from the efficiency of so many mothers after child-bed.

When advice is sought for symptoms of this nature shortly after labour, and a bally retroverted uterus is discovered on bimanual examination, it should be replaced and kept in position by a pessary. This is, however, but a small part of the management of such cases. The support by the pessary will probably allow of outdoor exercise being taken so that the general physical condition may be improved. Relief from indoor and exacting duties may be difficult to secure, but is a more essential matter than the pessary. If, as is usually the case, the patient is a tired and overwrought woman, a pessary is a poor substitute for the rest she needs. It is in regard to this type that the concentration on the medio position of the uterus so often fails to restore the woman to efficiency. Many of these tired mothers are referred to me because the position of the uterus is pitched on as the very head and front of the offending. On investigation the woman may have four or five young children, and little help with them and her household duties; she has a holiday of a few weeks each year, but the only change to her is one of venue, from her own house to rooms at the seaside, where escape from the children is even more difficult than at home. Perhaps she has never had more than a day or two's relief from her family cares, and it is not surprising that she should have the characteristic symptoms of the tired mother, that she is depressed and unfitted for her duties by aching back and legs. It matters little that her uterus is retroverted—it has been so for years; but it matters a great deal that she has relief from the constant strain that has worn her out and that her physical condition as a whole is improved.

Some of these women with simple retroversion have all the subjective sensations of prolapse; indeed, they often come with the complaint that "the womb drops," though they have no protrusion and nothing is discovered on examination, except that the uterus is lying back and perhaps a little low. Doubtless the symptoms are due to pelvic floor weakness with strain on the uterine supports. Great relief is usually effected by replacement and a pessary, by exercises similar to those described for the lying-in mother, by graduated outdoor exercise short of fatigue, and relief from the day-in and day-out strain of family and household.

In the course of three or six months, if the physical and nervous condition has improved, the pessary can be left out.

Such patients are liable to a return of their symptoms when run down or overtired, and some will ultimately develop definite prolapse, for which operative treatment will be required. The point I wish to emphasize in regard to these and similar cases is that pessary treatment alone will not suffice, but exercises and general management of the patient are essential to success.

Pessaries are valuable for temporary use—to give support till the patient's condition has so far improved that they are no longer needed. If the disability returns after removal of the pessary, some surgical procedure is far better than permanent pessary life.

The multitude of pessaries, intrauterine and vaginal, which marked the displacement era of sixty years ago, have almost all disappeared into museums as antiquities or curiosities, and now the ring is almost the only survivor. In the surgical era through which we are now passing the modern counterpart of the pessary inventor is the deviser of suspensory and sling operations on the uterus. The variations in detail of these procedures are legion, and the woman with a uterus that will not sit up straight can have a tack taken in its round ligaments, or have it held up by the ligaments being stitched to the abdominal wall, or delicately supported by the ligaments being clasped behind its back, and so on *ad infinitum*. The attitude of mind of these suspenders of the uterus is precisely that of the mid-Victorian pessary-monger; their methods only have changed with the times, and these operations are quite as much overdone as the pessaries were, but do less harm. There is not the bad mental effect of continuous pessary wearing with the recurrent need for changing, and there is the advantage that the patient has two or three weeks in bed with a change and convalescence, together with the strong suggestion that now her errant womb has been made right she also ought to be right.

Many of the women on whom such operations are done have an oversensitive nervous system, and at a time when their powers of resistance to disagreeable stimuli and sensations of fatigue are particularly low, owing to illness or overstrain, they are examined, the uterus found in the retroposed position, as it had been for long past, and an operation is promptly performed. When there is a fixed retroverted uterus with chronic inflammation an abdominal operation is necessary for the removal of the affected tubes, and it is as well to fix the uterine up at the same time. Suspensory operations may also be tried for sterility and repeated miscarriages, and in single women to get rid of a pessary or as a measure of desperation when all else has failed. Though they may be combined with operations for prolapse, alone they are not sufficient for that condition.

SUMMARY.

In case the arguments of my paper should not be obvious, its chief points may be summarized as follows:

1. Always look beyond the mere position of the uterus and do not ascribe symptoms to retroversion.
2. In retroversion accompanying pelvic floor prolapse, subinvolution, pelvic inflammation, and tumours, the disability is due to the primary condition and not to the position of the uterus.
3. Retroversion after child-bearing with subjective symptoms of prolapse is correctly treated by replacement of the uterus and a pessary, provided the relief of fatigue is also secured and attention paid to the general health, mental and physical, and to the improvement of the abdominal and pelvic muscles.
4. If recovery does not follow after six to twelve months operative measures will give better results than continued pessary treatment, and probably perineal repair and plastic vaginal operations will be more satisfactory than those of the hysteropexy type.

REPORTS of cases of epidemic jaundice have been received by the New York State Health Department from almost every part of the state, and the disease is epidemic in adjoining states.

DURING 1921 35 cases of leprosy were reported in New York, an increase of 7 as compared with the previous year; of these cases 12 were in municipal hospitals, while the others remained at home pursuing their usual occupations. All are periodically examined by an inspector of the Health Department, and treatment by chaulmoogra oil is regularly carried out.

THE NATURE AND SIGNIFICANCE OF HEART SYMPTOMS.

BY

SIR JAMES MACKENZIE, M.D., F.R.C.P., F.R.S.
(From the Institute for Clinical Research, St. Andrews.)

III.—HEART FAILURE.

WHEN anything is detected amiss with the heart the essential question for the practice of medicine is, "Does this sign indicate heart failure, or does its presence foreshadow its coming?" No examination, however elaborate, can be considered complete, no prognosis of any value can be given, and no rational treatment can be indicated unless these questions are satisfactorily answered. A knowledge of heart failure is therefore essential to the intelligent practice of medicine.

Definition of Heart Failure.

Heart failure may be defined as the condition in which the heart is unable to maintain an efficient circulation when called upon to meet the efforts necessary to the daily life of an individual. This definition is made wide and includes conditions of extreme failure as well as those where the failure is beginning. In the definition it was stated, "when called upon to meet the efforts necessary to the daily life of an individual," and this gives the clue to the symptoms of heart failure. It is a matter of common experience to find a person at rest presenting no physical sign of impairment when examined most carefully, yet on effort or certain kinds of effort symptoms are provoked which are due to the inability of the heart to meet the effort—that is to say, when at rest the heart is quite efficient, and its inefficiency is only found out when effort is made; and from this it is seen that the first signs of heart failure are shown by symptoms being called forth when the individual performs an effort which he is wont to do without any symptoms. The "response to effort" is therefore the sole guide in the detection of the early signs of heart failure.

CLASSIFICATION OF SYMPTOMS.

Most cardiac symptoms can be arranged in four groups, according to the structures which give rise to the symptoms, each group having also a particular significance.

1. *Symptoms due to lesions of the valves.*

The symptoms of this group may show the progressive effects of a disease where the valves are being damaged, as in the appearance of a murmur during an acute illness, or the gradual alteration of the murmurs, as in the slow progress of mitral stenosis. The kind of information conveyed by murmurs is that the valve may be the site or focus of an infective disease, or that the damaged valve may present an obstacle to the work of the heart muscle.

2. *Symptoms due to alteration in rate and rhythm.*

The kind of information furnished from this source is of a disturbance of some part of the conducting or reflex system of the heart—that is, of the parts concerned in the regulation of the heart beat and in the production and conduction of the stimulus that causes the contraction of the different chambers of the heart.

3. *Symptoms due to alteration in the size and shape of the heart.*

The kind of information conveyed by these symptoms is that the heart is distended by an increase of its contents (dilatation), or that its walls have become thickened (hypertrophy).

4. *Symptoms due to an inefficient output of blood from the heart—that is, the symptoms due to heart failure.*

THE SIGNIFICANCE OF SYMPTOMS.

It is to be observed that the first three groups of symptoms—that is, the modified sounds, variations in rate and rhythm, and alteration in the size and shape of the heart—do not give evidence of the functional efficiency of the heart. Diseased valves, abnormal rhythms, and increase in the size of the heart are so often associated with heart failure that they have come to be looked upon as evidences of heart failure; but this is a mistake. It may be

physical examination of the heart or by instruments do not give this kind of information. It cannot be insisted too strongly that though information of a useful kind can be obtained from these signs, they do not give the kind of information that is essential for rational practice. This warning is needed, for the attention given to physical signs tends to foster the idea that such signs are capable of revealing the functional inefficiency of the heart. The spectacular nature of this kind of examination makes the more important inquiry into the patient's sensations seem ineffective.

The Two Forces of the Heart Muscle.

As heart failure is first shown by a limitation of the field of the heart's response to effort it is necessary to recognize some of the features of the heart's power to accomplish its work.

As the heart possesses the power, not only of maintaining an efficient circulation when the body is at rest, but of varying its activity according to the bodily requirements, the force inherent in the heart muscle may be considered, for practical purposes, to be composed of two parts—that is to say, a part which is employed to maintain an efficient circulation when the body is at rest, and which therefore may be called the "rest force," and a part which is called into action when effort is made, and which may be termed the "reserve force." The rest force is the minimal force which the heart can exert to maintain the circulation at a level consistent with life. The impairment of this rest force produces those evidences of heart failure which persist when the body is at rest, such as dropsy and dyspnoea, and the continuance of such impairment eventually leads to a fatal issue.

The second part of the heart's force is that which is called upon when the body makes some effort. While the body is at rest this potential force is not exercised, but its possession enables us to undertake with ease all forms of effort. Inasmuch as this part of the heart's force is only used when exertion is made, it may appropriately be called the "reserve force" of the heart. Although we recognize what the reserve force is, it is not very easy to define it in words. Physiologists do not seem to have given it that study which its importance demands. Although difficult to define, its existence is proved in every movement of the body, and in every effort which is made, as it is by the possession of this faculty that we are able with ease to undertake all forms of effort.

Symptoms Produced by Failure of the Output of the Heart.

When an organ fails the evidence of its failure cannot usually be perceived by the study of the organ itself, but by the effects of its impaired function upon other organs. Heart failure means an output of blood from the heart insufficient to meet the requirements of the body, and if we possessed the power we might detect evidence of this limited supply in the various organs. All organs or systems may receive an insufficient supply. There are, however, only a few that give rise to perceptible symptoms, especially in the earlier stages. The first sign of heart failure is evoked by the organ or system which gives rise to the most prominent symptoms, and usually that system is the respiratory. Hence the reason that respiratory distress in response to effort is often the earliest sign of heart failure.

Symptoms Produced by Exhaustion of the Heart Muscle.

When the heart muscle itself receives an insufficient supply of blood, as in blocking of the coronary artery, it may give rise to symptoms when it is called upon to make an effort by reacting on the nervous system, and thus we often get pain on effort as the earliest sign of this kind of heart failure. The same kind of symptom arises when the heart muscle is exhausted from overwork or when supplied by impure blood or blood defective in some essential quality.

The Nature of the Symptoms of Heart Failure.

When we come to look into the mechanism of these two symptoms, respiratory distress and pain, we find that they are both due to a supply of blood insufficient for the effective functioning of certain organs. This is the aspect of heart failure which should be kept in view in describing the various features of affections of the heart. We do not yet possess sufficient knowledge to understand all the processes concerned in heart failure, but the more they are studied the more evident does it become that the symptoms of heart failure are to be found in the impaired function of organs that receive an insufficient supply of blood.

Signs in Advanced Disease of the Heart.

is necessary to keep this simple description of the initials of heart failure in mind. Obvious symptoms, as dropsy and enlarged liver, tend to divert attention to the subtle and more instructive signs. These obvious signs are late developments, and the mechanism of their production is fundamentally the same as breathlessness, in that they are due to the inability of the heart to maintain an efficient circulation in certain organs and tissues.

The Varied Symptoms of Heart Failure.

This presentation of the subject may seem so simple that it might be assumed that the recognition of heart failure is an easy matter. While the principle is simple its application is extremely difficult in the present state of knowledge. Finding that the main symptoms of heart failure are of the nature of sensations of distress experienced by the patient on exertion, we must know what questions to put to the patient, and we must be able to interpret his replies. The ability to do this can only be acquired after a long experience. Sensations of distress on effort may arise from many other conditions than a failing heart; those due to the heart must therefore be clearly distinguished from those due to other conditions. The sensations of distress are often brought out by response only to particular kinds of effort. Thus a mechanic with a damaged heart may be able to swing a sledgehammer all day, but is pulled up on going up a hill. On another day a man may walk ten miles, but he may be pulled on walking a hundred yards on a cold day.

Identical heart symptoms may arise when the heart muscle is diseased or when it is temporarily weakened from some passing infection. It is necessary to differentiate between these conditions. The severity of the distress may have no relation to the gravity of the condition. In one man slight pain may be of ominous significance; in another, pain of an agonizing kind may not be a sign of danger.

The signs of heart failure being mainly sensations of distress, it is useless to seek for a knowledge of heart failure from laboratory experiments. No doubt experiments reveal certain features, but they cannot give us the information necessary for the intelligent practice of medicine. Nor can such information be obtained from those who specialize in heart affections. This will at once become evident when it is realized that the symptoms of cardiac inefficiency are to be found, not in the examination of the heart, but in the symptoms produced by organs which do not receive a sufficient blood supply. Moreover, the heart is so often disturbed or weakened by disease in other parts of the body that an examination limited to the heart would of a certainty mislead.

The organ which receives a diminished supply of blood will give rise to symptoms peculiar to its function. We thus get a diversity of symptoms depending on the organs which are most affected, or rather whose symptoms are most in evidence. Therefore, to understand the symptoms of heart failure it is necessary to understand the symptoms produced by other organs. This kind of knowledge will never be acquired until we have a better understanding of the principles concerned in the production of symptoms. I have repeatedly called attention to the fact that so long as symptoms are incoordinated the study of disease clinically will merely result in an addition to a mass of chaotic details. When it is recognized that though symptoms are infinite in variety and in number the vital processes concerned in their production are few in number, it will be seen that with the recognition of these vital processes the chaotic mass of symptoms will be capable of classification according to their affinity in nature. This has already been demonstrated in describing the reflex process concerned in the movements of the heart. In heart failure the process concerned is an insufficient supply of blood, and each organ which receives an insufficient supply will show symptoms peculiar to its impaired function.

SUMMARY.

1. Heart failure occurs when the heart muscle fails to supply the organs of the body with blood sufficient for the efficient performance of their functions.
2. The symptoms of heart failure are therefore to be found in the symptoms produced by the impaired function of those organs that do not receive sufficient blood.
3. In the first instance this will occur only when the heart is called upon to exercise its full powers; the early symptoms of heart failure will only be produced during some physical effort.

4. This limitation of the field of response to effort is revealed by sensations of distress.

5. When symptoms of heart failure persist when the patient is at rest (dropsy, enlarged liver, orthopnoea) the reserve force of the heart is exhausted and the rest force is being encroached upon.

6. The symptoms of heart failure are not to be found by the examination of the heart.

DRAINAGE IN ABDOMINAL EMERGENCIES.

BY

A. CHURCHILL, M.B., B.S. LOND.,

LATE SENIOR HOUSE-SURGEON, BOLTON INFIRMARY.

VALUABLE papers have appeared from time to time in the *British Medical Journal* and *Lancet* emphasizing the importance of early diagnosis in acute abdominal crises. The responsibility for the heavy death rate of these conditions is in this way laid at the door of the medical attendant who is first called in to see the case.

It is an undoubted fact that the mortality amongst these patients increases in direct ratio to the time which has elapsed between the onset of symptoms and admission to hospital. Too often we have cases sent to the surgical wards which are more fit for the *post-mortem* room than for the operating table. Yet although so much depends on diagnosis, it is no use being blind to the fact that treatment in most of these cases is by no means a matter of universal agreement. Almost every step in our way of dealing with the commonest of abdominal emergencies is still open to controversy: the proper time for intervention, the site of incision, the mode of drainage.

Some surgeons advocate immediate operation as soon as a case of acute appendicitis is diagnosed; others prefer to wait until the crisis is over and operate *a froid*. McBurney's gridiron incision, Battle's incision, a paramedian incision with retraction of the rectus outwards, has each in turn been recommended as the incision *par excellence*. Last, but not least, drainage in the presence of free fluid in the abdominal cavity is a subject on which few agree. Scrubbing the fluid out, flushing the peritoneal cavity with lotions, the use of tubes, have all been advocated by eminent authorities. On the other hand, a school of surgeons teaches that the peritoneum is well able to look after itself, and that the less it is interfered with the better. No more scrubbing, no more flushing, no tubes, or only one where two or three were deemed necessary.

The 75 cases which form the basis of this paper seem to me to be of interest as having been treated on the lines of strictly limited interference. All the patients came from the working-class practice of a large industrial town, and the majority were not sent to hospital until several days after the onset of symptoms. They are thus anything but "picked" cases. I have purposely omitted four cases of general peritonitis who arrived moribund and died within twenty-four hours of their admission to hospital.

Technique.

The following rules were observed with regard to drainage:

- (a) Drainage was only carried out in the presence of free pus or thick purulent fluid.
- (b) The fluid was not scrubbed.
- (c) The peritoneal cavity was not irrigated.
- (d) Not more than one tube was ever used, this in the great majority of cases being placed in Douglas's pouch.

As soon as the patients had recovered from the effects of anaesthesia they were put in the full Fowler's position, the upper end of the bed being raised on blocks three feet high.

Among those treated are included cases of general peritonitis and of perforation of the stomach or duodenum. At the present day in many teaching schools the routine methods of drainage for such cases are three tubes in the renal, right iliac, and pelvic pouches.

Incision.

The incision varies with the condition present. In doubtful cases a right paramedian incision with retraction of the rectus outwards. In perforations of the stomach or duodenum a paramedian incision above the umbilicus with retraction of the right rectus outwards. In cases of general peritonitis a similar incision below the umbilicus. In the majority of cases of acute appendicitis, McBurney's gridiron incision; this was used in forty-eight out of seventy cases. Battle's incision was only used twice. In a few cases an oblique incision going right through the thickness of the abdominal parietes; this gives excellent access, but doubtless the risks of hernia formation are increased.

Where the position of the appendix is known before operation to be abnormal, as in Case 49, a suitable incision is used.

Only one case of hernia has been recorded as a sequence of the operation. The following table shows why operation was undertaken and the result:

	Total.	Recoveries.	Deaths.	Mortality.
Acute appendicitis without peritonitis	22	22	0	0
Acute appendicitis with pelvic peritonitis	29	27	2	6.8
Acute appendicitis with general peritonitis	5	4	1	20
Acute appendicitis with localized abscess	11	14	0	0
Perforation of the stomach or duodenum	5	5	0	0
	75	72	3	4

When there was a localized abscess the appendix was not removed in four out of fourteen cases. When the bowel was friable and the appendix difficult to reach it was thought safer to leave it behind. No. 37 was a child of 6, with peritonitis and died two days after the operation. A woman of 47, who died of portal pyaemia, was admitted. No. 58, a boy of 5, had a localized abscess and a gangrenous appendix. He died of intestinal obstruction. All these patients were operated on immediately after their arrival at hospital. It is open to question whether in No. 58 life might not have been saved by waiting until the acute condition was over before operating.

Complications.

These were: pneumonia, 1; pelvic abscess, 1; faecal fistula, 1; subphrenic abscess, 1; hernia, 1. The faecal fistula occurred in the case of a girl of 8 in whom the small intestines were matted together in such a way that the appendix had literally to be dug out of a mass of adherent bowel. During the process a loop of intestine was opened into. A faecal fistula developed which was successfully closed a month after the original operation.

Advantages of Limited Drainage.

The following advantages are claimed for the method of limited drainage:

- (a) Shock is diminished as time is saved, and the abdominal parietes are not interfered with to the same extent.
- (b) The after-treatment is less painful. Nothing is more nerve-shattering for a patient than the daily dressing with moving of three large tubes.
- (c) The formation of a faecal fistula is less frequent, most faecal fistulas being due to ulceration of the bowel by tubes.
- (d) Adhesions are not likely to form, and intestinal obstruction as an early or later complication is thus avoided.

Two of the perforation cases mentioned in this list were subjected six weeks after the first operation to a second laparotomy for gastro-jejunostomy. In both cases the only adhesions found were over the site of perforation just beneath the liver, and they did not interfere at all with the mobility of the stomach. Would this have been the case if several tubes had been used?

Swabbing the fluid out of the general peritoneal cavity or irrigating it with saline or antiseptics are procedures more likely to do harm than good by disseminating septic material and injuring the already inflamed peritoneum.

The objection which might be raised against the method of limited drainage is the additional risks it involves. As an answer to this it will be seen that out of 75 cases only two patients had secondary abscess formation.

The first patient (No. 34) had acute appendicitis of ten hours' duration, and very few people would have hesitated in closing the abdomen; the infection may have been very virulent. The other case (No. 75) had a very high gangrenous appendix just beneath the liver; the peritoneal cavity was drained, but contrary to rule the tube was not put in Douglas's pouch but behind the caecum, in the right renal fossa. A subphrenic abscess developed later. I am inclined to think that this complication would have been avoided by merely draining the pelvis, as we did in all our other cases. A tube often acts as a focus of infection; it irritates the neighbouring peritoneum and renders it less capable of self-defence. If placed at a spot where the peritoneum is not already inflamed it is more likely to act as a drain and not as an irritating agent. That is the reason why in most of our cases we drain not the appendix site but Douglas's pouch.

Amongst our other cases several were closed which had free turbid fluid in the pelvis. The majority healed by first intention. A few—amongst whom was No. 70, a perforated duodenal ulcer of two hours' duration—had a discharge

from their wounds a few days after operation. In other words, when there is an abdominal wound and fluid within the abdominal cavity, this fluid, if it does not become absorbed, finds its way out easily via the wound.

These considerations lead me to the belief that a restricted drainage of the abdomen than has been practised in the past involves no additional risks, whilst it entails advantages which make it a definite improvement in the surgery of emergencies.

SPLENOMEGALY WITH PROGRESSIVE ASCITES AND LOUD VENOUS HUM:

SPONTANEOUS CURE OF ASCITES BY LEAKAGE THROUGH ABDOMINAL WALLS.*

BY

ARTHUR J. HALL, M.A., M.D. CANTAB., F.R.C.P.,
PROFESSOR OF MEDICINE, UNIVERSITY OF SHEFFIELD; SENIOR
PHYSICIAN, ROYAL HOSPITAL, SHEFFIELD.

The following case, in addition to having features of diagnostic interest, eventuated in such an unexpected way that it seems worthy of record.

History.

A single man, aged 25, was admitted to the Sheffield Royal Hospital on June 21st, 1916, suffering from haematemesis. He is a coal-miner by trade. Up to the onset of his illness he had always been actively athletic, playing football regularly. He is a life-long abstainer and non-smoker. He has suffered from any previous illness except occasional attacks of "influenza."

On the day of onset, in April, 1916, he had worked three consecutive "shifts" in the pit—that is, practically, twenty-four hours without a break. During the third shift he felt pain in his stomach. For the next few days he was out of sorts, and then suddenly vomited about three pints of blood.

He was kept in bed for six weeks, feeling ill and weak. After this he began to improve, and was getting about, until the night of June 19th, when he felt sickly and restless. Next day he had another severe haematemesis in the evening and again, on the morning of admission, a still larger one.

On admission (June 21st) he complied with all the characteristics of an early chronic splenic anaemia:

1. Spleen enlarged to below navel.
2. Absence of enlarged lymph glands.
3. Anaemia of chlorotic type: red cells 1,350,000.
4. Leucopenia (5,000).
5. Liability to copious gastro-intestinal haemorrhages from time to time.

At that time there seemed no reason to doubt the diagnosis of splenic anaemia. The question of splenectomy was considered, and my surgical colleague and I agreed to wait until the profound anaemia following haematemesis had passed off before advising operation. During the next few weeks he improved. There was no recurrence of bleeding.

About the middle of July, 1916, the abdomen was found to be somewhat fuller, and to contain free fluid. The quantity was not large and it produced no symptoms. It appeared to be the type of ascites not infrequently found in cases of splenic anaemia, without necessarily connoting cirrhosis of the liver.

A very loud venous hum was now detected for the first time over the lower half of the sternum. The area over which the sound was heard extended from the level of the third costal cartilage above to the tip of the ensiform cartilage below, and for a short distance on either side of the sternum. The sound at the upper level was a typical "bruit de diable," such as is heard in the neck of chlorotics. It became gradually louder as the lower end of the sternum was approached, and, suddenly, on reaching the ensiform cartilage, its intensity became extremely increased, so that it might be described as a continuous "roar." At this latter area a thrill could be felt on light palpation, disappearing on firm pressure. The sound was slightly increased during inspiration, but was continuous throughout the respiratory cycle. There were no visible veins.

During this time the anaemia showed little improvement in spite of treatment, and he had one or two attacks of epistaxis. Towards October, 1916, the ascites began to increase very much, so as to necessitate tapping on October 20th. After this it refilled rapidly and the tapping had to be repeated nine times during the next three months, varying

* An account of this case was given at the meeting of the Association of Physicians held at Birmingham in May, 1921.

quantities, up to 13 pints, being removed each time. About Christmas the lower abdominal wall became sore, and on other attempts to tap him it was impossible to get any quantity of fluid away. Abdominal section was considered, it owing to the condition of his abdominal wall it was thought to be very undesirable.

After this the man's condition was deplorable. The abdomen was greatly distended, there was secondary oedema of the legs, and it was necessary to keep him almost continuously under morphine on account of the constant pain on distension. It seemed certain that he would die.

As regards diagnosis, the progressive ascites with rapid loss of flesh following his early symptoms of splenic anaemia made cirrhosis of the liver seem probable—in fact, typical picture of Banti's disease, except for the rapidity of progress, which was measured in months instead of years. This view was supported by the presence of the loud venous hum over the sternum, such as is occasionally found in cases of hepatic cirrhosis.

About the end of January, 1917, a remarkable change gradually came over the scene. The abdominal walls had become greatly distended, and there were large numbers of "lineae atrophicae." Through these stretched areas of the lower abdominal wall the ascitic fluid began to ooze out at various points. The oozing continued night and day for the next few weeks. Dressings were applied constantly to soak up the fluid, and during the next week or two the abdomen began to diminish in size. The pain became less, so that morphine was no longer required. His appetite returned and he put on flesh. Week by week he improved steadily, and in April, 1917, one year after the first onset of symptoms, and about three months after the oozing had begun, it ceased completely and he was able to get about. Since then he has made an uninterrupted recovery.

I examined him in May, 1921, four years after he had left hospital. He was then in good health, well nourished, and able to do his work and enjoy life, though somewhat less strenuously than before his illness. The spleen is just as large as it was when I first saw him in June, 1916. He does not look pale. There is no increased fragility of the red cells. There is no ascites. There has been no further haematemesis. The venous hum is now limited to an area about the size of a halfpenny, situated over the middle line opposite the sixth costal cartilage. It is much less loud than before. There is a very faint thrill on light palpation.

REMARKS.

The venous hum was first heard in July, 1916, soon after the second attack of haematemesis, at the same time that a certain amount of fluid was first detected in the abdomen. How long the murmur had been present is uncertain. When first heard it was so loud and obvious that it could hardly have been missed had it been present when he was examined on admission about a month earlier.

Thayer¹ has given a detailed account of recorded cases of venous hums heard over and about the abdomen. These vary widely in position and degree according to circumstances. They may or may not be associated with visibly enlarged cutaneous veins. In four cases the sounds described correspond so closely to that in my case that their similarity of origin seems probable.

Rolleston² quotes a case under Ogle at St. George's Hospital of a man, aged 58, who died of cirrhosis of the liver. A loud murmur had been heard during life behind the sternum, and at autopsy the left internal mammary vein showed a varicose condition in this region. It then turned inwards to the falciform ligament and ran into the left lobe of the liver, joining the left branch of the portal vein.

He also records a case of his own, a man aged 43, who died of cirrhosis of the liver. There was a continuous bruit in the epigastrium, resembling the "bruit de diable" heard in the neck. The falciform ligament contained a thin-walled vein as large as the little finger. He says: "When the hum is loudest over the lower end of the sternum above the lower margin of the liver it is probably produced in a dilated coronary vein, or in a dilated communication between the internal mammary vein and branches joining the portal vein."

In all these cases the presence of cirrhosis of the liver was either proved at autopsy or was strongly suspected during life. So far as I can ascertain, no case having a similar loud venous hum audible in this particular situation—namely, over the xiphisternum—has been recorded in any other pathological condition than cirrhosis.

Spontaneous Restoration of Portal Equilibrium.—I have not been able to find a record of any case of ascites which has similarly cured itself by multiple leakings through the

abdominal wall. Jenner³ published a case in which, after several tapings, the abdominal wall close to the navel burst with a loud report, but whether the result was satisfactory or not I do not know.

DIAGNOSIS.

As the patient is still alive the actual pathological conditions must, for the present, remain a matter of speculation. It is possible to exclude certain alternatives. Thus there is no question of alcohol, as the man is a life-long abstainer. Syphilis may also be excluded, as the blood gives a definitely negative reaction. Gancher's disease is rare, and in the absence of any family history, known occurrence in childhood, or typical stigmata of the disease, such a diagnosis is not supported by the facts of the case. Familial splenomegaly is negated by the absence of family history, of jaundice, and of increased fragility of the red cells. The absence of jaundice also excludes biliary cirrhosis.

The diagnosis, therefore, seems to rest between:

1. A primary portal cirrhosis—not due to alcohol.
2. Thrombosis of the portal vein.
3. Splenic anaemia (with or without cirrhosis of the liver).

As regards (1) primary portal cirrhosis (not alcoholic), we may set the rarity of such a condition in adults, the absence of any early dyspeptic symptoms, the very large hard spleen preceding any recognizable ascites, and the complete cessation of progress when portal equilibrium was re-established.

There are several points in this case which seem to fit in with the diagnosis of (2) portal thrombosis. In the first place there is the sudden onset of symptoms. His first abdominal pain came on whilst he had been at hard manual labour at the "coal-face" for nearly twenty-four hours. We may assume, therefore, that he was not anaemic to any extent previous to that time. This alone is not pathognomonic, because it is familiar knowledge that in typical splenic anaemias patients usually do not present themselves for treatment until the spleen is already very large, and must therefore have been enlarging for some time without producing symptoms sufficient to require treatment. If, however, this abdominal pain marks the onset of portal thrombosis, the occurrence of severe haematemesis a few days later would also be explicable on the same grounds.

I am informed by his medical attendant, Dr. West Jones of Eekingtoo, that the spleen was enlarged to a considerable extent whilst he was attending him before admission, but there is no exact record as to when it was first noticed. The onset of progressive ascites in the late summer would suggest further extension of thrombosis to other branches of the portal vein. The course and progress of the case are also consistent with this diagnosis. His profound anaemia when first seen in June, 1916, could be sufficiently accounted for as "post-haemorrhagic."

If the diagnosis of portal thrombosis is correct it would seem that now his obstruction is relieved he is so much, the same condition as a man who has recovered from a femoral thrombosis, whose only inconvenience is the mechanical damage which the obstruction has caused to the affected leg. In his case the mechanical damage is an enlarged spleen and probably a good many abdominal adhesions.

There is considerable evidence, both clinical and pathological, that cases of portal thrombosis simulate splenic anaemia very closely. Parkes Weber⁴ recorded such a case in a woman. The onset dated from a confinement in August, 1910. She had ascites, enlarged spleen, and severe haematemesis five years later, from which she never recovered. At autopsy thrombosis of the portal tract was found. There was no cirrhosis of the liver. Galloway⁵ also recorded a case in a man, aged 28, with splenomegaly, leucopenia, recurrent haematemesis, and ascites. Splenectomy in his case was followed by death in ten days. At autopsy there was no cirrhosis of the liver, but definite portal thrombosis.

Similar cases have been known and recorded previously. Langdon Brown⁶ in his review of pyelothrombosis and suppurative pyelophlebitis, mentions a case which was admitted into St. Bartholomew's in 1872 and had been diagnosed as portal thrombosis twenty years before admission. The patient was a woman, aged 48. She had pain in the left side twenty-six years previously, following the birth of her second child. Haematemesis occurred at intervals; the spleen reached to the navel. At autopsy the portal vein was found to be a mere cord with fine lumen. The liver was normal. It is interesting to note that in the report of this case no mention is made of ascites having been present, in spite of the extent of the thrombosis.

As has been pointed out by others, there is no certainty, even if portal thrombosis is the only lesion found at autopsy, that it has caused the condition or even preceded the onset of splenomegaly. Even if it has done both we are still left in doubt as to what has been the cause of the thrombosis.

On the whole I am inclined to look upon this as a case of "portal thrombosis." Possibly the further course of the case may show more definitely the underlying pathological condition. Meanwhile the question arises, Should splenectomy be advised now? Considering the very large size of the spleen, the probable existence of considerable adhesions in the abdomen; and the fact that he is practically free from symptoms, I think the answer should be in the negative.

With an Historical Account of the Development of Flocculation Tests for Syphilis,

BY

J. C. G. LEDINGHAM, C.M.G., M.B., CH.B., F.R.S.

(From the Lister Institute, London.)

Our only excuse for placing the following notes on record is the fact that hitherto comparatively few collated results of parallel Wassermann and Sachs-Georgi tests have appeared from laboratories in this country. It will doubtless be the policy of the near future to institute carefully planned investigations on the great scale dealing with parallel complement-fixation and flocculation tests with a view to the selection of the best working methods and the correlation with clinical experience of what may prove to be the future routine serological test for syphilis. Pending the appearance of such massed statistics it may be of interest to record the capabilities of a flocculation test performed with material sent from outside sources to the diagnosis department of this institute accompanied by clinical data of varying completeness. Our series comprises only 265 serums forwarded to the institute during the period July to October, 1921. One of us (B.) carried out the routine Wassermann tests, while the other (P.) undertook, solely as a matter of research, the parallel flocculation tests.

METHODS EMPLOYED.

Flocculation Tests.

Two antigens were employed throughout ("D" and "L"), and the results with both are summarized. Antigen "D" was that of Bordet and Ruelens (1919), with the addition of cholesterol as recommended by Dreyer and Ward (1921), and the latter's technique was strictly adhered to so far as qualitative diagnosis was concerned, no attempt being made in this short series to probe the possibilities of quantitative evaluation. A dropping apparatus was used, and for the first 122 serums five tubes containing dilutions of serum varying from 1 in 1.25 to 1 in 26.4 in a total volume of 25 drops were put up. Later, as the results from the first tube were indefinite, and as a large quantity of serum was required, the first tube was dispensed with. The mixture of antigen, saline, and serum was incubated at 37° C. for seven hours in a water-bath, and the results then read. One batch of antigen was employed throughout, and was preserved in a cool incubator at a temperature of about 22° C. Antigen "L" was simply an alcoholic extract of guinea-pig's heart muscle, to which was added a 1 per cent. solution of cholesterol in the proportion of 9 parts of heart extract to 1 of the cholesterol solution.

For the first 132 cases four tubes were put up, containing in a total volume of 26 drops a constant quantity of pure serum (6 drops) and 20 drops of a dilution of antigen varying from 1 in 20 to 1 in 80. For the remaining half of the series the antigen was kept constant in the four tubes (20 drops of a 1 in 40 suspension) and the serum was varied from 1 drop to 6, the total volume being made up to 26 drops.

The dilutions of serum in the tubes were therefore 1 in 3, 1 in 6.5, 1 in 13, and 1 in 26. The serums had been previously heated at 54° C. for 90 minutes. The tubes were incubated for five hours in a water-bath at 37° C. and the results were read 20 minutes after

removal from the bath. They were reread after standing at a temperature for twelve to fourteen hours.

One batch of this antigen "L" was used throughout. Experience showed that preservation in the cold (about 4° C.) was most satisfactory. Results with both antigens were recorded as "standard" (easily visible to the naked eye), "trace" (visible with lens), and "negative." At each test controls were used—namely, one Wassermann-positive serum, one Wassermann-negative serum, also previously tested positive and negative Sachs-Georgi samples. The antigen was also put up alone to exclude any non-specific precipitation.

Wassermann Tests.

These were performed with the antigen employed here—namely, an alcoholic extract of guinea-pig's heart muscle, to which is added before the test a 1 per cent. cholesterol solution in the proportion of 5 parts of extract to 4 parts of the cholesterol solution. Of this antigen a 1 in 90 dilution was used.

RESULTS.

Total number of serums tested	265
O	91
P	85
P	71

The degree of agreement may be otherwise expressed for the antigens used, thus:

W+ L+ ...	83	W+ D+ ...	71
W- L- ...	171	W- D- ...	171
W+ L- ...	8	W+ D- ...	20
W- L+ ...	3	W- D+ ...	3
Total ...	255	Total ...	265

Thus, comparing the Wassermann and the flocculation tests: "L" antigen the total number of discrepancies in the series was 11, or 4.1 per cent., and in the case of "D" 23, or 8.6 per cent. The 91 positive Wassermann tests are classified as 70 "full positive," 10 "partials," and 11 "slight partials." Corresponding to this grouping the results with "L" and "D" are as follows:

	Total Positive.	Full Positive.	Partial Positive.	Slight Partial.
W	91	70	10	11
"L"	83	67	9	7
"D"	71	61	5	5

Thus 5 of the 8 missed positives with "L" are accounted for by partial and slight positive Wassermann reactions. The 3 missed by "D" antigen are similarly accounted for. Only three serums yielded positive results with both "L" and "D" antigens, while the corresponding Wassermann tests were negative. In all three the flocculation tests were recorded as "trace" reactions. One was from a latent case under treatment and in which the Wassermann test had been positive seven months previously; another was untreated and was stated to have a rash on trunk and perforation of palate (certainly a suggestive history); while the third came with no particulars.

Treated and Untreated Cases.

One hundred and fifteen of the series were stated to be treated cases, while 150 were entered as untreated or "no particulars." They are thus grouped:

	Total.	W+.	"L" +.	"D" +.
Treated	115	31	28	23
Untreated	150	61	55	48
Total	265	91	83	71

Primary Cases.—There were 20 cases of primary sore, in 9 of which spirochaetes were found. They yielded 9 positive results by all three methods.

Only 5 cases of nerve syphilis appear in the list, with a yield of one positive result with the Wassermann test, the corresponding flocculation tests proving negative.

Discussion.

It has been customary to take the discrepancy percentage as a measure of the efficiency of a flocculation test, and on this basis the results from our small series compare favourably with those recorded by other workers in this country who have published results within the last eighteen months. The discrepancy percentage, however, must in the meantime be regarded solely as a provisional measure of efficiency. The ultimate interpretation of discrepancies between complement-fixation and flocculation tests must, as Lesser (1919) has wisely pointed out in a paper dealing with results by three different methods (Wassermann, Meinelke, and Sachs-Georgi), rest with the clinician, whose record of the past, present, and future clinical course of the case and response to treatment will materially assist the serologist to appraise with some confidence the results from different methods and to eliminate those which prove unsatisfactory. The flocculation test may indeed prove, as Dreyer and Ward suggest, to fit the clinical facts even better than the Wassermann. Even now, with some sixteen years' experience of the Wassermann test, doubtful reactions are constantly occurring (especially in treated cases), and the correlation of these with parallel flocculation tests may serve to place the latter on a proper footing with respect to the clinical condition in the diagnosis of which it is designed to participate. So far, the agreement

between Wassermann and flocculation tests carried out under the best auspices is remarkably good, and there is every reason to expect that further extensive experience of parallel tests in relation to syphilitic disease will lay a sure foundation for the flocculation test as the future test of election for syphilis.

THE DEVELOPMENT OF FLOCCULATION METHODS.

It is, we think, of prime importance that the profession should be familiar with the historical development of a test which, now that the time seems favourable, may have a chance of establishing itself as the method of choice.

The Wassermann reaction dates from 1906, when the paper by Wassermann, Neisser, and Bruck appeared. This test, which at first was regarded as a true antigen-antibody reaction, was made possible by the demonstration in 1901 by Bordet and Gengou that, in the reaction between antigen and antibody, complement, if present, was fixed and consequently rendered unavailable for completion of haemolysis in a haemolytic system. In the following year (1907) it was shown by Landsteiner, Müller and Pötzl, Levaditi and Yamaouchi, and Porges that the effective substance which reacted with syphilitic serum was not present solely in organ extracts of luetic cases, but also in extracts of normal organs. Further, this effective substance was shown by them to be contained almost solely in the alcohol-soluble fraction, its association therefore with a lipoidal substrate being thus demonstrated. In this same year Michaelis noted in one single instance the formation of a visible precipitate when the extract of a luetic liver was brought in contact with a luetic serum. He concluded wrongly that this observation supported Wassermann's view of the specific character of the Wassermann test as a true antigen-antibody reaction. However, chance observation as it was, it gave the impetus to those attempts which have followed each other down to the present time to substitute for the complicated system of the Wassermann reaction a straightforward flocculation test involving two ingredients only. Following this isolated observation of Michaelis, Porges and Meier (1907, 1908) were the first to probe the possibilities of practical application, and, curiously enough, they chose to work, not with alcoholic organ extracts, but with commercial lecithin preparations (from egg yolk), the capacity of which to act as antigen in the Wassermann reaction had already been demonstrated. For many reasons, however, and more especially the instability of the lecithin suspensions and the occurrence of flocculation with normal serums, the use of lecithin was discontinued, and in later work by Porges, in collaboration with Elias, Neubauer, and Salomon (1908), resort was had to the use of sodium glycocholate, a salt possessing colloidal properties in solution, and which Levaditi and Yamaouchi had previously found to function as an antigen in the Wassermann test. Porges states that with this salt as antigen results were achieved which approximated in accuracy to those yielded by the Wassermann test; but it would appear that no thorough testing of flocculation methods was possible or practicable at this period, the Wassermann test in all its many modifications and improvements claiming the undivided attention of serologists and clinicians alike.

In the meantime the properties and mechanism of action of lipoids in serological reactions were being minutely investigated by numerous workers. Among them Sachs and Rondoni (1909), in the course of a study of the antigenic powers of lecithin in the Wassermann reaction, demonstrated an increased action of lecithin in the presence of sodium oleate, and in the following year (1910) Browning, Cruickshank, and McKenzio demonstrated the remarkable action of cholesterol in increasing the amount of complement absorbed in the presence of a mixture of lecithin and luetic serum. Taking advantage of this discovery, Herman and Perutz (1911) mixed cholesterol with sodium glycocholate with the object of obtaining a more visible flocculum in the presence of syphilitic serum. This modification proved in Herman and Perutz's hands more sensitive than the original technique of Elias, Neubauer, Porges, and Salomon with the glycocholate alone, and yielded positive results in certain luetic cases when the original method gave no visible flocculation whatever. Meanwhile the flocculation of these lecithin suspensions again drew attention to the study of the inner mechanism of the Wassermann reaction. Was the complement really fixed by virtue of a precipitin reaction? No visible precipitation, apart from chance observation, was noted, which might account for the fixation of complement

in the presence of alcoholic organ extract and luetic serum. Jacobsthal (1910), however, succeeded in demonstrating by the ultra-microscope the occurrence of floccular masses, the development and growth of which could be followed. He even attempted to employ the method practically, and stated that absolutely negative results occurred with non-luetic serums, but the percentage of positive results was not quite so high as in the Wassermann-positive series.

This work was followed up by Bruck and Hidaka (1910), who found that, by the aid of the centrifuge, precipitates, small indeed in bulk, could be obtained after some prolonged contact of alcoholic liver extract from foetal livers with luetic serum at a low temperature. With the object of making this precipitate more bulky, and consequently more visible, they added mastix to the system, and with this technique it was possible to obtain results approximating to the Wassermann, but a fair percentage of discrepancies occurred. The outcome of this form of study was to support strongly the view that the Wassermann reaction depends primarily on fixation of complement by an invisible precipitate (nascent precipitate) taking place in the earliest stage of the interaction between the alcoholic organ extract and the luetic serum. Apparently the only difficulty now was to secure an extract sufficiently sensitive to show visible precipitation in the presence of luetic serum. Hecht (1916) had definitely successful results, but the most recent and definitive stage in the development of flocculation methods as practical diagnostic aids was reached towards the end of the war, when Meinecke (1917) and Sachs and Georgi (1918) came forward with tested procedures, the latter of which (by Sachs and Georgi) is likely, either in its original or more possibly in some modified form, to become the method of election.

Meinecke's method is known as the two-stage method, and in its ordinarily practised form (the so-called salt method) is carried out on the following lines, purely technical details being omitted:*

An ordinary Wassermann extract in distilled water dilution, and containing no cholesterol, acts as antigen. Mixtures of inactivated serum and antigen in this salt-free medium are kept at incubator temperature for twenty-four hours. At the close of this period all tubes should show flocculation, whether they contain normal or luetic serum. The second stage now commences. A definite amount of a sodium chloride solution of previously determined strength is run into each tube. After an hour's further sojourn in the incubator the tubes are read, when it is found that in the Wassermann-negative series the flocculi are dissolved up, while the Wassermann-positive series remain permanently flocculated.

The salt concentration determined from previous experiment is that which will in one hour just completely dissolve the flocculi in the normal controls, so that differences can be elicited as between strongly positive, weakly positive, doubtful, and negative series.

The Meinecke reaction appears to be a perfectly straightforward and feasible test. It has been tried by many workers in Germany, generally in conjunction with the Wassermann and with the Sachs-Georgi reaction presently to be described. On the whole, however, it has found much less favour than the latter.

With their experience of complement-fixation technique, and their intimate knowledge of the comparative values of simple alcoholic organ extracts and purified lipoids as antigens, Sachs and Georgi (1918) chose as antigen an alcoholic extract of bullock's heart (hearts of other animals are, however, admittedly suitable), to which cholesterol as an absolutely indispensable adjunct is added. For the Wassermann test it is of course not indispensable, though sufficiently advantageous to make its use almost universal, but for the flocculation test its presence is essential for visible precipitation. The cholesterolized alcoholic extract is diluted with five parts of physiological saline. One c.cm. of a 1 in 10 dilution of the inactivated patient's serum is mixed with 0.5 c.cm. of the diluted extract along with the necessary controls. The tubes are left either for two hours at 37° C., and then overnight at room temperature, or they are kept continuously at 37° C. for eighteen to twenty hours. Positive reactions are read as + + +, + +, and +, while the control serums remain clear or slightly opalescent. Both Meinecke's and Sachs and Georgi's reactions have been extensively tested in large series, and a summary of results in over 12,000 cases by various workers who compared the Sachs-Georgi with the Wassermann reaction in parallel series yielded a conformity

* In flocculation procedures technical details are all-important, but those interested must refer to the original papers cited below.

percentage with the Wassermann of no less than 92.44 per cent. (Sachs and Georgi, 1920).

The most recent advance is that of Dreyer and Ward (1921), who follow in principle the method of Sachs and Georgi, but prefer as antigen, on the ground of greater stability, one recommended by Bordet and Ruelens (1919) for Wassermann tests. To this antigen, which, according to Bordet and Ruelens, can itself be flocculated in the presence of inetic serum, Dreyer and Ward add cholesterol. They claim that with a stable antigen and a refined technique involving the quantitative expression of all degrees of flocculation, the test so conducted can lend itself to accurate standardization in terms of standard units.

Time and experience on the large scale will show how far this claim is justified and compatible with practicability in the hands of average workers, whose power to translate visual impressions into arithmetical language is notoriously variable. In treated cases particularly, the superiority of quantitative readings in flocculation tests over the purely qualitative evidence of the Wassermann would be warmly acknowledged, and it is to be hoped that the extensive parallel series which we understand are in contemplation may furnish important information on this point.

The above sketch is concerned solely with methods based on the mutual interaction of organic colloids and takes no account of the various and, on the whole, unsatisfactory tests which involve merely the precipitation of serum globulins by electrolytes.

RESIDUAL VACCINES IN ACUTE BACTERIAL DISEASES.

BY

C. E. JENKINS, M.R.C.S., L.R.C.P.,
PATHOLOGIST TO SALFORD ROYAL HOSPITAL.

WHEN a dose of any vaccine is administered the extent of the resulting general reaction is beyond control. In chronic disease and where prophylaxis is intended it is possible to adjust the dose so that the reaction, if any, is small and therefore negligible. But cases which are acutely ill may, and usually do, react violently to a dose which would cause only trivial malaise in the other types of cases. The reason for the lack of control lies in our inability to gauge the effect before administration.

Another objection less frequently heard is to the effect that the patient is already "full of toxins," and any addition is not likely to improve his state. The argument is so plausible that its hypothesis is overlooked and suffered to pass unquestioned. The patient is not "full of toxins" until he is moribund; and since that is a clinical estimation, the lethal amount of toxin may have been reached before or after the patient is estimated to be in that condition. The objection also appears to presume that the human organism is a kind of pot into which a fixed amount of toxin may be poured. In any case the criticism misses the mark as far as residual vaccines are concerned, for they contain neither toxin nor endotoxin. It is evident that lack of control is the real bugbear, and I believe that the system about to be described is one which goes some way towards meeting the difficulty.

The treatment of acute sepsis does not permit delay, consequently it is not justifiable to wait for the preparation of

an autogenous vaccine. A stock vaccine may be below an autogenous in efficiency, but the prospect of success in a given case would be placed in far greater jeopardy by two or three days' delay before commencing treatment.

To be generally useful a stock vaccine must contain the organisms that are most likely to cause such conditions as septicaemia, pyaemia, peritonitis, cellulitis, and large carbuncles associated with grave toxic disturbance. Two vaccines were therefore prepared: the first contained equal numbers of the streptococcus, pneumococcus, staphylococcus, and diphtheroid bacillus; the second contained the colon bacillus instead of the pneumococcus—in other respects it was the same as the first vaccine. A certain degree of discretion is needed to decide which of the two is the more suitable in a given case, but as a simple guide it may be said that the first is intended for all purposes except septic conditions of the abdomen and pelvis, in which the second will be found more generally useful.

A stock vaccine was frequently required in the out-patient department, and the opportunity was taken to note the largest dose that most walking chronic cases could tolerate without a general reaction. A minority showed a reaction with this dose, but they were ignored because it is impossible to assess individual idiosyncrasy on a graduated scale.

The vaccine was next tried with acute cases, starting with very small doses, and increasing them as experience demonstrated their lack of effect. A dose was ultimately reached, which was capable of producing marked clinical improvement without causing any discernible clinical reaction. This was true of the great majority; a small minority reacted with undesirable intensity, and the problem they presented still awaited solution. The dose was one-third that of the corresponding dose in the chronic cases, and was approximately 80 millions of the mixed organisms. It will be observed that the vaccines were standardized upon a physiological basis. This method is, in the author's opinion, more exact than the counting methods, which are notoriously only accurate, as far as can be discovered, to within about 40 per cent. This dose, suitable for acute cases, was termed the standard dose.

The solution of the difficulty presented by the minority was found in a close study of the clinical manifestations of the effects of the vaccines. The following facts emerged:

- (a) A general reaction in an acute case will be seen, if at all, in six to ten hours after injection.
- (b) An improvement will make itself evident in nine to eighteen hours.
- (c) It will be admitted that, if two doses of a vaccine are given within a few minutes of each other, the effect will be as if one dose equal to the sum of the previous two had been given. It was found that this rule invariably held good for all periods up to twenty-four hours, and was commonly true up to forty-eight hours.

These three items taken together offer a simple method of dealing with the matter.

Since the lengths of time in (a) and (b) are appreciably shorter than in (c) it is possible to give a fraction of the standard dose, then observe its effect, and if neither reaction or improvement occurs the second fraction can be administered next day. Any reaction following this second fraction is either very mild or, more frequently, so small as not to be recognizable clinically. After the first dose has been completed, in one or two portions, no farther vaccine should be given for at least four days; it is better to wait five or six.

The system is very simple in operation and gives such reliable results that there is some danger of it generating a belief that the clinician is working with a remedy of very feeble potency, and that he can do as he pleases upon occasion. When a first fraction produces no result of any sort and the second a marked improvement without visible reaction there is a temptation to "continue" the benefit by giving a third fraction on the third day. If this is done the resulting general reaction may be very disconcerting, and although permanent harm has not ensued, for a few hours the aspect of the patient has been such as to deter me from any further excursions in the same direction.

It is not every case that needs a second dose, or a second fraction of the first dose. The first dose is frequently sufficient to be a turning point in the course of the disease, enabling the patient to recover without further stimulation.

The rapidity with which improvement can show itself throws an interesting light upon the question of a "negative phase" in connexion with this type of vaccine. The patient's tolerance to a second dose is not established for some four or five days after the first dose, and during that time he is

abnormally sensitive to the vaccine, yet the clinical change for the better appears in a much shorter time, and we may therefore only conclude that the patient's general resistance does not coincide with his resistance at the focus of infection. This is demonstrated in a remarkable manner in cases of large carbuncles accompanied by grave toxic symptoms. The disappearance of the slate-blue colour round the lesion and its replacement by a bright red erythema is a striking change that occurs in a few hours. A possible explanation is that the first antibodies produced by the vaccine are all removed from the circulation as quickly as they are formed by some process of concentration at the site of infection. Whether the inflamed tissues in that area play an active or a passive part in this fixation of the antibodies is a matter of speculation at present.

The following cases are the first few treated with the vaccine, and nearly every one illustrates some point discussed above. The cases have not been "selected," but are a true consecutive series.

Case 1.—Aged 26. Septic finger due to running dirty scissors into it. Next day, small pustule, lymphangitis, and axillary adenitis. The finger was fomented and the lymphangitis disappeared, but swelling of the whole digit commenced. Serum only on incision. General lassitude. Vaccine given on seventh day. Next day the swelling was rapidly subsiding; there was distinct tenderness at the point of original injury. Pus visible that evening; on incision, a large quantity escaped and there was complete relief from pain. Next day, a clean granulating surface, which was completely healed on the fourth day after administration of vaccine.

Case 2.—Aged 11. Streptococcal peritonitis, apparently idiopathic. Abdomen opened, drain inserted; prognosis hopeless. Vaccine given twenty-four hours later, up to which time the patient was moribund and apparently dying. Herein failed to calm the patient. Six hours after vaccine was given the patient went quietly to sleep, temperature and pulse fell, the former several degrees, and the case made an uneven recovery.

Case 3.—Pyæmia; purulent arthritis of right elbow with abscesses in axilla and groin. Temperature 105° to 102.2° ; pulse 100 to 120. Vaccine given. The next day the temperature was still swinging, but on the down grade. A second dose was given four days later, and temperature and pulse settled finally on the tenth day.

Case 4.—Aged 11. Acute osteomyelitis of spine and infection of nail. Prognosis hopeless. Vaccine given on the sixth day at 11 a.m. That evening the temperature rose half a degree, but the next morning was down one degree; the pulse fell from 140 to 110. The patient was operated on that afternoon, and died early next morning.

Case 5.—Carbuncle of hand, involving half of palm, index finger, and back of hand; acute toxic symptoms and swelling of arm; tissues blue-grey in appearance. Prognosis very serious. Vaccine given; no reaction, but tissues had lost blue colour within twelve hours; the carbuncle was surrounded by deep scarlet erythema, hot to the touch; toxic symptoms much less. Not content with this a second dose was given next day, and caused an alarming reaction for a few hours; then all passed off. A large slough separated on the eighth day, and a clean granulating surface was left which healed rapidly.

Case 6.—Infant aged 8 months. Furunculosis and toxæmic absorption; sleeping badly. Vaccine given and child taken home. Next day there was great improvement; the child slept well from then onwards. The mother volunteered the statement that the lesions had changed colour from blue to red. No sign of a general reaction. No further treatment needed.

Case 7.—Acute appendicitis, large burst abscess, and peritonitis in a female aged 40. She appeared to be doing well for three days after operation, then became worse—abdomen distended, anxious facial expression, wound drain diminished, temperature and pulse rising. Vaccine given, with prompt improvement within sixteen hours; there was better, and the patient looked much better, and the second dose was given forty-eight hours later, caused the patient to feel very unwell, and for a few hours the medical attendant had grave doubts as to her recovery. Next day she seemed better than ever, and eventually made a complete recovery.

Case 8.—Phagedænic primary sore of penis; widespread septic infection of groin; advanced pyorrhæa. The patient was in a filthy personal condition. Streptococcus isolated by blood culture. Vaccine given on two occasions without clinical benefit; no reaction at any time. Ulcerative endocarditis found at necropsy.

Case 9.—Acute osteomyelitis in a patient aged 10. Bone opened up and drained, but temperature remained for seven days after operation at about 103° , with no sign of subsiding. Vaccine given, and temperature fell to 98° six hours later, and was 97° in another eight hours.

Case 10.—Pyæmia. Patient was ill three weeks before vaccine was given. No reaction or benefit after both fractions of the first dose, so a week's interval was allowed to elapse before giving a second dose. Again no reaction or improvement, so another week's interval was ordered. The third dose was then given, with the same result. All three doses were the same size.

Case 11.—Primary sore of penis with severe balanitis, becoming gangrenous in one part. Vaccine caused a small slough to separate,

with total disappearance of the surrounding swelling, and a small clean sore. No sign of a general reaction.

Case 12.—Subacute cellulitis of leg. Chronic indurated which was subject to periodical acute exacerbations. Cleared up the condition promptly. No general reaction observed.

Case 13.—Streptococcal septicaemia. Patient had been fourteen days when residual vaccine was first given. A p dose with the common toxin-containing vaccine produced reaction which lasted several days and from which no good was derived. The first dose of the author's vaccine produced result of any sort, and a second dose four days later also made any impression. The temperature remained at about all the time. The patient died four days after the second was administered.

These cases cannot be called promising from the point of collecting a good "record" of results, but the author has acted in accordance with the belief that a remedy only be tested thoroughly when it is given an opportunity as well as to succeed. In no instance was the smallest sign of an undesirable result due to the vaccine.

One fact is very clear: vaccine treatment can cure other remedies have been tried and have failed, but the results can only be expected when the vaccine is given early as possible in the disease. It cannot be expected to resuscitate those with the death rattle already in their throats, although on occasion it seems to have come to near to it.

The most important feature of all these cases is that in no case where the fractional dose system was followed any alarming general reaction occurred. The cases demonstrate the author's main contention: it is possible to administer a vaccine to a patient suffering from acute sepsis in a manner that the vaccine is under control and the residual susceptibility of the patient prevented from causing a disastrous reaction. The system in brief is:

1. The largest dose that most chronic walking cases tolerate without a general reaction is ascertained.
2. One-third of this dose is called the standard dose, administered to an acute case in two halves.
3. If after the first fraction there is neither a general reaction nor improvement, the second fraction should be given within twenty-four hours.
4. If the first dose requires both fractions, the amount the dose should be considered to be that of the sum of two fractions.
5. The second dose should not be given for at least days after the completion of the first dose, and can be same size as the first or increased by not more than ten per cent. If a result has been obtained with the first dose, doubtful if an increase of amount in the second is of advantage.
6. It is as well to prepare two stock vaccines—one containing the streptococcus, pneumococcus, *Staphylococcus aureus*, and Hoffmann's bacillus; the other having the colon bacillus substituted for the pneumococcus, but otherwise the same as the first vaccine.

The author is much indebted to Mr. Roy R. Kerr, F.R.C.S., for providing some of the cases, and most particularly for close clinical observation, which was largely instrumental in furnishing the facts upon which the system of treatment advocated has been built.

THE PARASITOLOGY AND CLINICAL ASPECTS OF MALARIA IN ANTIGUA.

BY

W. M. McDONALD, M.R.C.S., L.R.C.P.,
DISTRICT M.O. AND M.O.H., ANTIGUA, WEST INDIES.

There has not, hitherto, been any investigation into the parasitology of malaria in Antigua. The following observations, based on a record of 300 positive blood films, may have value in providing an accurate indication of the nature of the infection with which we have to deal. Of the 300 positive blood films which were analysed 61 per cent. showed *Plasmodium falciparum* (malignant tertian), 28 per cent. *Plasmodium malariae* (quartan), and 11 per cent. *Plasmodium vivax* (benign tertian). The predominant infection, therefore, is *Plasmodium falciparum*.

The form of parasite most frequently found was the malarial form, but it is worthy of note that the classical sign of malarial infection was conspicuous by its rarity. The majority of parasites seen were in the tenue form. In most cases

which the ring form was retained, the usual form seen was a linear or circular central nucleus, surrounded by a blue body, which, as it grows, shows a thickening at one side. The largest subtertian rings seen were about one-quarter of the size of the red cell; these can be differentiated from a benign ring, first, by the sharply defined outline and decided thickening on one side (the side farthest from the nucleus), a benign ring of the same size being flimsy and ill defined, and showing a uniform thickening in contrast to a one-sided thickening. Secondly, it can be differentiated by its effect on the red cell which contains it; in a subtertian infection the containing cell is normal in size and colour—that is to say, where there is general anisocytosis or anisochromia, the affected cell may vary in size or colour within the same limits as unaffected cells, whereas, when the parasite is benign, the affected cell is always swollen, paler, and distorted, and often shows Schüffner's dots. The subtertian ring, moreover, frequently has a double nucleus, whereas this is very rarely seen in a benign ring. The difference in colour, size, and shape of the affected cells is, however, so marked that there is no difficulty in distinguishing between a benign and a subtertian ring form.

The greatest difficulty occurs in distinguishing between a young quartan and a young subtertian parasite. The young quartan often has a double nucleus, and the affected cell is generally slightly smaller than normal. I have found that the young quartan shows a more intense colouring than the subtertian, and that it does not develop the characteristic one-sided thickening of the protoplasm that the subtertian does. In a quartan infection it is usual to find two or three stages of growth in the same film, whereas in a subtertian rings only are found, or rings and crescents. I have found on only two occasions the sporulating form of the subtertian parasite in the peripheral blood; the spores were smaller and paler than in the similar stage of quartan or benign parasite; one showed thirty small spores and the other seventeen, while the pigment was black, whereas in quartan it shows yellowish-brown in the sporulating stage. Sporulating bodies are commonly found in quartan infection, the number of spores varying from 5 to 15, but averaging 8 to 10, and the spores are large and stained deep red. In the benign parasite the spores vary from 12 to 25 in number, they are much more crowded together, and the pigment is neither central nor clumped. In fact, in my experience the benign tertian parasite never assumes what is known as the "rosette" form; this form is limited to quartan and subtertian infections. Crescents were found in 32 per cent. of the subtertian cases. This is of interest in view of the fact that many authorities believe that crescents are very rarely seen in the peripheral blood.

In a recent article in the *Lancet* by Majors Pratt-Johnson and Gilchrist, it is stated that "crescents are not found in the untreated or in acute cases of the disease." My own experience does not agree with this statement. The cases in which crescents were found were all untreated cases, or at any rate cases which had not been recently treated, and whereas crescents alone are not found in acute cases, yet in many cases of acute illness crescents are found at the same time as the rings. In only three cases did I see Maurer's dots. It would appear that these dots are not dependent on differences of staining, but on some particular factor which has not yet been determined. Pigmented mononuclear cells were found in about 60 per cent. of cases. The chief characteristic of the differential count is a marked increase of large mononuclears and large lymphocytes, a reduction of small lymphocytes to about 3 per cent. of the total count, and a low polymorphonuclear percentage. Eosinophils are normal or slightly increased. The chief characteristic of the red cells is a marked anisocytosis; this is always present and varies only in degree. Abnormal changes, such as polychromasia and basophilic stippling, are sometimes seen.

Clinical Aspects.

The most striking characteristic of malaria in Antigua is the association of the subtertian parasite with clinically mild symptoms. The generally accepted view is that this parasite shows far greater pathogenicity than either of the other two varieties. Here, however, in Antigua, although *Plasmodium falciparum* is the commonest variety found, yet its malignant manifestations are apparently limited almost entirely to young children. I say "apparently" because I believe that further investigation will prove that the malignant nature of parasite manifests itself locally, not so much in malignant as of fever as in the sequelae which, developing at

varying intervals after a malarial paroxysm, have not hitherto been attributed to their true cause, which is malaria. I may mention in this connexion that I have recently seen three cases of nephritis, one of which was fatal, in which *P. falciparum* was found in the blood.

As a general rule, however, this infection is associated in the adult with mild symptoms. The cases under review are patients who have been well enough to walk some miles to the surgery for treatment. The temperature is low, between 99° and 101°. Cases which exhibit a definite forty-eight hours' periodicity are the exception rather than the rule. The usual type is a low fever exhibiting a mild quotidian paroxysm and sometimes a double quotidian. As a rule the spleen is not enlarged, and subjective symptoms are not marked, the patient complaining of slight pains in the limbs and general malaise, which, however, is not sufficiently marked to prevent him from working. Young children, on the contrary, suffer severely and are often acutely ill as a result of malarial infection. I have seen many cases of convulsions and coma in young children, due to infection with *P. falciparum*. The younger the child the more acute are the symptoms. In the series of cases under review there are only five fatal cases, all being children under ten years, all being associated with convulsions or coma, and all being due to *P. falciparum*. This infection is undoubtedly a very grave factor of infantile mortality.

Plasmodium malariae (quartan) exhibits a slightly different symptomatology. Patients seldom seek medical aid for a simple quartan infection. Practically all the cases which have come under my notice exhibit a quartan triplex infection, in which parasites of several different stages of growth are found at the same time, and the resulting pyrexia is quotidian. The patient, as a rule, complains of nothing beyond the fever, which clears up readily under quinine treatment, but relapses more frequently and more persistently than other infections.

Benign tertian infection shows a sharp paroxysm and a more definite periodicity, but yields more readily to treatment than either of the other two varieties. I have seen only three cases of mixed infections, the parasites found in one case being crescents, malignant rings, benign rings, and benign sporulating bodies; the other two were malignant and benign, and malignant and quartan, respectively.

Treatment and Relapses.

Owing to the fact that the cases under review are surgery patients who cannot be kept under observation or followed up it is impossible to give a scientifically complete treatment to any case, but as far as the treatment of the actual malarial attack is concerned I find that the essentials of successful treatment are (1) initial dosage with calomel and salts, and (2) large doses of quinine. The initial dosage with calomel and salts is of the greatest importance, as this makes the action of the quinine much quicker and surer. In the cases of adults I give 30 to 45 grains of quinine daily. Cases clear up very quickly under this treatment. Patients are recommended to continue quinine treatment, but as a matter of fact they never do. It is not possible, therefore, to give any treatment with a view to avoiding relapses. In this connexion it is of interest to note that relapses do not appear to be more frequent than in places where energetic anti-relapse treatment is undertaken. I have records of relapses in about 8 per cent. of the total number of cases. This record is not scientifically accurate, as the cases are not under observation, and many others may have relapsed without coming up for treatment. The greatest number of recorded relapses are quartan cases, with malignant next; and in this particular series none of the benign cases have relapsed. Of the comparatively small proportion of cases which I have been able to keep under observation I can write with certainty of the absence of relapse in the following:

Malignant (acute) treated by one intramuscular injection and 30 grains quinine daily by mouth	2 cases.
Treated 18 months ago; no relapse	1 case.
Treated 13 months ago; no relapse	1 "
Malignant; treated for 3 days only, 14 months ago; no relapse	1 "
Malignant; treated 10 months ago	1 "
Malignant; treated 3 months ago	1 "
Quartan; treated 9 months ago	1 "
Quartan; treated 5 months ago	1 "
Quartan; treated 14 months ago—one intramuscular and oral treatment	1 "

These ten cases did not receive any quinine treatment after the initial attack had subsided. In the small proportion of

cases treated by intramuscular injection four relapses are recorded. In no case did any local trouble occur as a result of intramuscular injection.

General Remarks.

In concluding this report I would draw attention to the connexion between the malaria incidence and the death rate. Our death rate is more than twice as great as that of England and Wales; and while deaths recorded as directly due to malaria provide only 2½ per cent. of the total, yet due weight should be attached to the probability that malaria, on account of its effect in lowering the resisting power of the body to other infections, is a contributing factor to many more deaths than those of which it is the direct or recorded factor, and that, further, there are strong indications that malaria sequelae are responsible for many deaths which are recorded as due to other causes. In view of these facts it cannot be too strongly represented that vigorous anti-malarial measures should be instituted throughout the island with a view to (a) lowering our excessively high death rate and (b) improving the quality and quantity of our labour supply.

THE APPLICATION OF FASCIA LATA IN PLASTIC SURGERY.

BY

CYRIL H. CUFF, M.B., B.S.DUNELM., F.R.C.S. EDIN.,
RESIDENT SURGEON, VICTORIA HOSPITAL, ST. LUCIA, BRITISH
WEST INDIES.

In a previous article¹ I ventured to enumerate some of the uses to which the fascia lata might be applied in plastic surgery. I now wish to illustrate, by a series of cases, some of the suggestions already put forward. The operations subjoined have all been carried out during the last two years, and the results, on the whole, have been encouraging. Technique must be most careful, and every effort in reconstruction should be based on strictly anatomical lines wherever possible. I have also found it advantageous to have no "slack" after suturing the fascia lata *in situ*, but rather to have the graft under slight positive tension.

CASE I.

A man was admitted to hospital suffering from a faecal fistula in the left iliac fossa the result of an old gunshot wound of abdomen. The fistula communicated with the descending colon, and was about the size of a shilling. There was no spur, and the finger could be passed freely in both directions. Operation took place on January 27th, 1920. The opening was surrounded by a free incision one-sixth of an inch from edge, the bowel mobilized, and margin of the opening infolded by a series of Lembert sutures. A portion of fascia lata from the thigh, 2½ inches by 4 inches, was sutured with medium catgut over the deficiency in the oblique muscles from the rectus sheath medially to the remains of the external oblique aponeurosis laterally. Tension in the skin wound was obliterated by a pedicle flap turned down from the left hypochondriac region. The wound healed under one dressing, and when last heard of in December, 1920, the patient was doing well.

CASE II.

A man, who had sustained a gunshot wound of left forearm, was admitted with partial wrist-drop and inability to extend fingers or thumb at terminal phalanges. He had a long scar along the upper half of the posterior aspect of forearm, and some obvious loss of muscle substance. An operation was performed on May 18th, 1920, a long exploratory incision being carried over the scar, extending to the wrist. Upper portion of the extensor muscle was found to be healthy; the lower portion and communis tendons in the upper part were an adherent mass of fibrous tissue. Tendons just above posterior annular ligament were healthy. The intervening scar tissue was freely excised, and the communis and extensor longus pollicis tendons identified below. The extensors of the carpus were freed from the overlying scar tissue. A fascial flap 4 inches by 1½ inches was cut from left thigh and split in its lower half. The upper portion was sutured to the healthy belly of the extensor communis digitorum and longus pollicis, the hand and fingers being in a position of dorsiflexion. The lower divided portion was sutured to the communis tendons and longus pollicis. The hand was put up in a long "cock up" splint, sutures removed at the end of three weeks, and gentle passive movement commenced. At the end of two months a fair degree of movement in the fingers was obtained, and even more in the thumb, but on the whole the benefit was less than anticipated.

CASE III.

A man was admitted with an old gunshot wound of the middle third of left shin. There was a painful adherent scar, about 2 inches long, about the middle of the subcutaneous border of tibia. At the operation on April 22nd, 1920, the scar was freely excised, also the underlying scar tissue. The edges of wound were

undercut and two parallel tension incisions made, 1 inch from sides of wound. A flap of fascia lata 2 inches by 1 inch was sutured to the periosteum, with the fatty side subcutaneous, and the wound closed without tension with three sutures of "bipol silk." The result was very satisfactory, the new scar remaining elevated and painless.

CASE IV.

A man was admitted suffering from an old gunshot wound of the mandible with non-union and loss of substance on the left side. There was a gap of 1 inch midway between the symphysis and angle. The fragments were largely subcutaneous, as there was loss of masseter and facial muscles, and the skin was adherent to the bone. Operation was performed on July 5th, 1920, a curved incision being made, commencing at the lobule, to the symphysis. Fragments were freed from skin and scar tissue, sclerosed tips excised, and a gutter cut in them in the usual manner with an Albee saw. A graft was cut from the tibia 2½ inches long and secured in the gutter with kangaroo tendon. A strip of fascia lata 4 inches by 1½ inches was then carefully wrapped around the graft and sutured to periosteum of fragments. The skin was closed with horseshair. At first there was some serous discharge, which lasted for nearly a month, but finally the wound closed and the result was very satisfactory. The fascia lata probably saved the graft in this case.

CASE V.

A man was admitted to hospital suffering from hernia of the right lung, through the third interspace, about the nipple line. There was a tympanic swelling, about the size of a coconut, and a marked impulse on coughing, reducible on pressure. The conditions had followed upon an old injury to the chest by the shaft of a cart. Operation was performed on September 8th, 1920, a large curved incision being made from the anterior axillary fold, across the right chest and down towards the ensiform cartilage. The pectoralis major was split about its centre, and the sac (formed by the parietal pleura) dissected off the thin and stretched pectoral muscle and ribs. The third and fourth ribs were found to be widely separated. During this dissection, the sac was accidentally incised and air rushed in. The opening in the pleura was closed with a purse-string suture of catgut, and the sac, after being separated, was invaginated through a defect in the intercostal space. Following upon a suggestion of Professor Rutherford

poma, situated over the Into two portions, and into 4 inches by 2½ inches was stretched firmly over this and sutured to the divided and separated periosteum of the rib above and below. The pectoral muscle was then adjusted and the wound closed. A report dated January 12th, 1921, states that the chest in the position of rest is quite flat, and with the hardest cough the patient is only able to produce a small impulse without any bulge.

CASE VI.

A pensioner was admitted with "drop-foot," the result of nerve injury consequent upon a gunshot wound of the thigh. Previous operations for nerve suture and for tendon transplantation had failed. At an operation performed in June 29th, 1920, the tendo Achillis was lengthened subcutaneously, the base of the fifth metatarsal and tubercle of scaphoid exposed through small incisions, and the crest of the tibia and fibula exposed through a 3-inch curved incision at the junction of lower and middle thirds. The aponeurosis of the tibialis anticus and peronei was split in the line of incision, and the periosteum of both bones exposed. Fascia lata of right thigh was exposed through a 12-inch incision, and a portion 12 inches by 2 inches removed. This was split from below upwards for 7 inches, thus resembling a pair of trousers. The upper portion was sutured deeply to the periosteum of the tibia and fibula, and to the split aponeurosis. The lower bifurcated portion was pulled down by tunnelling the subcutaneous tissues with forceps, and a limb drawn into each of the two lower wounds. Here with the foot in full dorsiflexion all slack was taken up, and the two strips sutured to the periosteum of the scaphoid and the fifth metatarsal respectively, and to the plantar fascia. The wounds were closed with silk worm gut and a back splint applied. In January, 1921, he could walk well without any special boot.

CASE VII.

A man was admitted with partial rupture of the short head of the biceps of the left arm, the injury having occurred three months before admission. On examination, there was a small hard nodule at the junction of upper and middle thirds of the left arm, on the medial aspect, and above this, a definite hollow. Movements of flexion and supination were weak and very painful. An operation was carried out on September 20th, 1921, a long incision being made from the coracoid, along the antero-internal aspect of the upper arm to the junction of middle and lower thirds. The scar in the biceps was located just about the junction of the two heads. The site of the scar was firmly adherent to the underlying brachialis anticus. Adhesions were separated, and the tendon of the short head, which was torn and slack, tightened up. A strip of fascia lata, 4 inches by 2½ inches, was then wrapped round the site of rupture, and secured with catgut sutures. A further small portion was sutured over the scarred area on the brachialis. The wound was closed in two layers, and the arm slung in a "dog collar," in semiflexion. At the time of writing the arm is gaining power daily, and movements are free from pain.

I have selected these cases as fair examples of the practical uses to which the fascia lata may be put. It has, of course, been utilized for many other purposes, and doubtless others will yet be devised.

I wish to thank the Council of the Northern Counties Medical Society, Morison, and Dr. W. K. Russell, for permission to include Cases v and vi.

A CASE OF SLIPPING PERONEAL TENDONS TREATED BY KELLY'S OPERATION.

BY

D. W. HUME, M.B., B.S.LOND., F.R.C.S.ENG.,
MEDICAL SUPERINTENDENT AND SENIOR SURGEON, MINISTRY OF
PENSIONS HOSPITALS, EXETER.

W. B. F., aged 22, was admitted to the Ministry of Pensions Hospital, Streattham Hall, on July 10th, 1921, complaining of pain and weakness in the right ankle, and inability to walk any distance.

History.

He stated that while at physical training in June, 1918, he fell and twisted his ankle rather badly. The injury was diagnosed as a sprain, and he was sent to hospital. Nothing definite was discovered on x-ray examination, and his leg was put on a back splint for five weeks. After this he was given massage for six weeks, followed by a stay of two months in a convalescent camp. He was demobilized in January, 1919. For some time after this his ankle swelled at night, and his leg and foot were put in plaster for seven weeks, but, after the plaster was removed and he was treated by massage and exercises, there was still some swelling of the ankle at night, and, on extreme flexion or extension of the foot at the ankle-joint, something slipped on the outer side of the joint, giving rise to much pain locally and a jarring sensation up his leg and body.

Condition on Admission.

On admission the movements at the ankle-joint were good, and there were no signs of any disease of the joint, but on dorsiflexion a distinct slipping of the peroneal tendons could be felt. A skiagram did not show any damage to the ankle-joint. An operation for retaining the peroneal tendons in their normal position was necessary, and I decided to perform that described by Mr. R. E. Kelly in the *British Journal of Surgery* for April, 1920.

Operation.

On January 26th, 1921, I made a hockey-stick-shaped incision immediately behind the fibula, commencing at a point about 2½ inches above the lower extremity of the bone, and

Diagrams illustrating the method of cutting the wedge. The wedge is shown wider than is necessary. The dotted lines indicate parts of the wedge in the slot in the bone.

following the course of the tendons downwards. The incision was deepened and the periosteum covering the outer surface of the fibula was incised and stripped, so as to expose the outer surface of the bone and its anterior and posterior borders. The peroneal tendons with their synovial sheath were retracted with the periosteum stripped from the posterior border. At a point about 1½ inches from the lower end of the fibula on its anterior border, and midway between its external and internal surfaces, a hole was bored horizontally backwards through the bone with a small bone awl. This hole was enlarged downwards and parallel to the external surface with a Gigli saw, and when the cut was large enough to admit the point of a Hunter-Mackenzie saw, this instrument was used, until the cut reached a point about half an inch from the extremity of the bone. Two cuts were now made in a horizontal direction but approaching one another posteriorly to join the vertical cut, so as to free a wedge-shaped piece of bone with its narrow end at the posterior border of the fibula. The saw was sloped while making these cuts, so that the external surface of the wedge was narrower than the internal surface. The wedge thus formed could only be removed from the bone by sliding it forwards, and when it was pushed backwards and tapped gently it became fixed in the groove made by the saw cuts, with about a quarter of an inch projecting from the posterior border of the

bone, thus making an external lip to the peroneal groove. It was found, however, on attempting to bring the superficial tissues together over the bone, that there was a tendency for the wedge to slide forward in its groove, but this was easily prevented by raising the floor of the groove slightly in front of the wedge with a chisel. After the wound had been closed, the foot was put in plaster, with a window over the incision, in a position of plantar flexion.

Result.

The plaster was removed one month after the operation, and recovery was uneventful. The movements at the ankle-joint were perfect, and no slipping of the tendons could be obtained. The patient states that he is cured, and that he has none of his previous difficulties in walking.

A skiagram taken six months after the operation showed the wedge firmly fixed in the position in which it was placed.

The main difficulty in the operation is, as pointed out by Kelly, the thickness of the saw. Allowance has to be made for this in the inclination of the horizontal cuts to one another, so as to avoid too great projection of the posterior part of the wedge when driven into position. A small fretsaw, such as is used by watchmakers, would be an excellent tool for this operation, and I propose to use it in future cases. It is also rather difficult to avoid injuring the synovial sheath of the peroneal tendons, and I accidentally made a small opening into it in this case, but no harm resulted.

THE INTERPRETATION OF SYMPTOMS IN DISEASE OF THE CENTRAL NERVOUS SYSTEM.

ABSTRACT OF THE GOULSTONIAN LECTURES, DELIVERED
BEFORE THE ROYAL COLLEGE OF PHYSICIANS,

BY

ANTHONY FEILING, M.D., F.R.C.P.,
PHYSICIAN, HOSPITAL FOR EPILEPSY AND PARALYSIS, LONDON.

LECTURE III.

In this final lecture Dr. Feiling said that he proposed to deal with some of the more general rather than the particular aspects of disease of the central nervous system. Any discussion on the interpretation of symptoms could not fail to take account of the principle laid down by that master mind of modern neurological theory and practice, Hughlings Jackson, who distinguished between negative and positive symptoms, a negative symptom implying some definite loss of function, and a positive some accelerated function. The actual symptom-complex produced by disease provided, more frequently than not, both positive and negative symptoms, destructive lesions producing the latter, and irritative lesions the former. The term "irritative," as applied to a pathological lesion, must not be interpreted too narrowly, in the sense of a mere mechanical irritation. Brief or temporary circulatory disturbances might be included in such a category, and the convulsions or deliriums occurring in various states of toxæmia were to be regarded as positive symptoms produced through the medium of the circulation. It must be understood also that when a destructive lesion occurred in the nervous system it did not follow that the ensuing disorder of function was necessarily due to that destructive lesion itself; it might be due, wholly or in part, to the unbalanced action of other parts of the nervous system.

Negative and Positive Symptoms.

The same morbid process might produce at one and the same time negative and positive symptoms. The early stages of syphilis of the central nervous system, for example, might be marked by pain—a positive symptom—while later on negative symptoms in the shape of palsies made their appearance. A more difficult question to decide was whether pain and other subjective sensory disturbances could occur as the result of purely destructive lesions, for this would seem to imply that positive symptoms could be produced by such lesions.

The lecturer did not wish to suggest that in investigating any disease of the nervous system it was necessary to set out by classifying symptoms as negative and positive. It was only necessary to realize that there were these two kinds of symptoms, and from such realization one was led to consider the nervous system as a whole. The consideration of these principles had its value when one was confronted with the task of localizing a lesion in the central nervous system. It was notorious how misleading in such cases the signs might

be. A palsy of the sixth cranial nerve, occurring as a late event in intracranial tumour, furnished an illustration of a late sign which frequently had little or no localizing value.

Disorders of the Cerebral Circulation.

In the two previous lectures he had been concerned principally with symptoms arising from disease of the central nervous system itself; but it was a matter of everyday experience that many of the symptoms of which patients complained were to be interpreted as disorders of function produced by temporary or recurring disturbances in circulation. Such disturbances might be quantitative, as anaemia or hyperaemia, or qualitative, in which there was some chemical or biochemical alteration in the blood itself. Symptoms referable to the nervous system formed a not inconsiderable part of nearly all forms of cardio-vascular disease, but there were many other conditions in which disorders of the cerebral circulation played a leading part. One of the previous Goulstonian lecturers (Dr. Risien Russell, in 1909) had dealt fully with disorders of the cerebral circulation, so that it was not necessary for him to cover the same ground. It was well known how epileptiform convulsions, quite indistinguishable from those of ordinary epilepsy, might occur in many toxic states—eclampsia, lead poisoning, and so forth—and typical epileptiform convulsions might be seen in cases of heart-block constituting the Stokes-Adams syndrome. There seemed to be some common ground between all these different conditions where the immediate or proximate cause of the convulsion could be fixed. Such cause, to his mind, lay in some disorder of the cerebral circulation, and on this point he was in absolute agreement with Russell as well as with many others.

It became a principle of some importance, therefore, to regard a fit as a symptom only, and not as a disease *sui generis*. Mr. Percy Sargent, in his presidential address to the Neurological Section of the Royal Society of Medicine, had related that in a series of 270 cases of brain tumour operated on by him a fit was the first symptom complained of in 40 per cent. This was probably an unusually high proportion, for there were many cases of cerebral tumour in which fits never occurred at all, and, in addition, many cases of cerebral tumour which never found their way into the hands of a surgeon. The mere presence of cerebral tumour was not of itself sufficient to cause a fit. It was the same with injuries; one might hazard the assumption that there were probably a great many people nowadays with foreign bodies embedded in their skulls who did not suffer at all from epilepsy.

The Cause of Epilepsy.

The textbook descriptions of the fits of epilepsy and of hysteria led the reader to suppose that there was a great distinction between them. In practice such distinction was not always evident, and increasing experience had taught the lecturer the great difficulty of making a diagnosis in some of the periodic attacks of apparent loss of consciousness which he was called upon to treat. It was, of course, well recognized that many epileptic attacks might be precipitated by various psychical conditions or emotional stresses. Recently an attempt had been made to include epilepsy among the group of diseases or symptoms which might be said to have a psychogenic origin. Such an explanation might seem at first sight fantastic, but there were certainly cases where attacks similar to those of idiopathic epilepsy had yielded to psychological treatment. There was another school, which would include epilepsy among the group of so-called toxic idiopathies, thus bringing it into line with such conditions as asthma, hay fever, and urticaria; and here also there were cases which seemed to support this view. Whatever might be the exact physical production of epilepsy, the final cause must, to his mind, lie in a disturbance of the cerebral circulation.

It was only in comparatively recent years that the involuntary nervous system had received much attention at the hands of clinicians, who were just beginning to realize the wide part which it played in the production of symptoms. It would be wise to recognize that multiple causes might be at work. Perhaps observers were too much occupied with symptoms in attempting to correlate disturbances of function with actual structural disease. Even in cases where actual structural disease of the central nervous system was present, *post-mortem* examination would not always succeed in connecting symptoms with the actual morbid anatomy.

"Organic" and "Functional."

In conclusion the lecturer spoke on the use and abuse of the terms "organic" and "functional" as commonly employed in connexion with disease of the nervous system. In investigating cases of disease of the central nervous system it was in reality disturbances of function which were studied rather than alterations in structure produced by disease. Hence the continued use of the terms "organic" and "functional" might be misleading. The term "functional" had gradually become identified with the broad meaning of "hysterical" and on looking more closely into the results produced by this abuse of the term it would be found that it was diseases in which permanent changes in the reflexes occurred which were called organic, and that unless such changes could be demonstrated there was a great risk that the case would be called functional. No doubt many of these cases were really functional, but the special connotation which this term had come to possess made its application deceptive. The distinction between organic and functional, although at first useful, had ceased to serve its purpose. The necessary distinction was between symptoms caused by physical influences and those caused by mental influences only. Physical changes might be permanent—such as gross destruction of nerve fibres; or they might be temporary—such as circulatory defects or alterations in the volume or composition of the blood. Similarly with mental or psychical factors: these might induce bodily reactions which persisted and led to permanent changes in bodily functions; yet no one would speak of a disease like diabetes as functional. It was illogical, he maintained, to identify the term "functional" with the term "hysterical." The term "functional" could very well be dispensed with altogether, for all diseases of the central nervous system were functional in the sense that a disorder of function was produced. What it was really necessary to know was whether or not a disease was due to permanent structural change in the tissues, and, if it was, whether the cause was physical or mental, or both. The attempt to draw a hard-and-fast line between organic and functional nervous disease was fraught with no little danger. Equally misleading was the idea that there must be two classes of neurologists, one to deal with organic and the other with functional cases. It was to be hoped that no such distinction would be recognized. The nervous system functioned as a whole, and should be studied as a whole.

Memoranda:

MEDICAL, SURGICAL, OBSTETRICAL.

HYPERPYREXIA DURING INFLUENZA.

G. C., a school teacher, aged 42, was some years before this recorded illness an in-patient at Bath Hospital suffering from haematemesis (and subsequent thrombosis of the veins of the leg), and during her seven months in hospital is stated to have registered a temperature of 110° F.

During the month of March, 1919, she complained of "pains across the shoulders; back of the head, and neck." Examination revealed nothing save a slightly furrowed tongue and an axillary temperature of 107° F. On advising the relatives to have a consultant's opinion, in view of the hyperpyrexia, they expressed little or no anxiety, as she had "had a higher temperature before at Bath."

Dr. Carey Coombs saw the case in consultation on the following day. There was no evidence of any organic disease. The axillary temperature registered 110° F. It was taken by me personally, using two thermometers, one in each axilla. The thermometers were both graduated to 113° F., and appeared capable of registering not more than 114.5° F. That same evening the thermometers registered 113° F. +, which fact I communicated to Dr. Carey Coombs. The patient at this time complained simply of headache. On the third day the temperature fell steadily to the region of 104° to 105° F., and remained so for several days, only to rise about the fourteenth day again to 113° F. +. Though the columns of mercury filled, in both cases, the capillary to the utmost limit, neither thermometer was broken as the result of the patient's hyperpyrexia.

After an interval of some two or three weeks a third rise, terminating as before by lysis, was registered.

After fourteen weeks' treatment at home (during which time the patient lost several stones in weight) I was sent for

on June 10th as the patient was again complaining of "headache." The temperature registered was 107° F. This was apparently the commencement of the fourth "exhibition," and I at length persuaded the patient to go into hospital. On June 11th, in hospital, the temperature registered 104.5° F. After that day, in spite of an attack of Vincent's angina, her temperature for the most part remained subnormal for the succeeding nine weeks. The patient is still alive, and is now under surgical care for a Colles's fracture.

The "exhibition" comment by Dr. Carey Coombs (written on the from hospital in August, 1919) appears in :

I saw this patient at her own home with Dr. W. G. McKenzie. We neither of us had any doubt that the very high temperatures recorded prior to admission were genuine. One evening temperature recorded was 114° F., and there were others nearly as high. During these hyperpyrexial crises she looked very ill, but neither then nor at any other time did she display signs of any organic cause. Indeed, when she did have a good excuse for fever (Vincent's angina) nothing out of the way happened.—C. F. C.

SLIPPING RIB.

LUXATION of lower costal cartilages, to which Mr. Davies-Colley has given the appropriate name of "slipping rib," cannot be very rare. I have met with a few cases.

Some time ago an was admitted to this hospital suffering in a very similar way to the examples given by Mr. Davies-Colley. Although, with the stoicism of his class and nationality, he bore with the disability for some years, he had to give in to it at last and seek relief. In his case it was the ninth rib on the left side which was at fault. As the interchondral articulations often include the ninth costal cartilage, I took the condition to be a luxation of this joint. I treated it in a way precisely similar to that which Mr. Davies-Colley practised—namely, excision of about three inches of cartilage and rib. The result was perfect relief from unbearable pain.

I have a case of the same condition at present under my care; the costal cartilage of the ninth rib on the right side slips easily upwards and forwards. The condition gives rise to no pain and the patient does not complain of it, having other troubles of a more serious nature.

R. B. MAHON, M.Ch., F.R.C.S. Eng.,
Surgeon to Galway Central Hospital.

THROMBO-PHLEBITIS OF THE FEMORAL VEINS FOLLOWING LOBAR PNEUMONIA.

THE extent of venous thrombosis in the lower limbs following right-sided lobar pneumonia appears to warrant the publication of the following case :

On January 4th, 1922, a girl, aged 22, had an attack of influenza; her in rather a debilitated condition. On the I was called to see her as she complained of severe pain in the right side of the chest, especially on taking a deep breath. The temperature was 103°, pulse 100, respirations 40. Physical examination of the chest revealed lobar pneumonia in the lower lobe of the right lung. For the next six days she was very ill, but on the seventh her temperature dropped by crisis and she fell into a comfortable, undisturbed sleep.

For the next day or so she made good progress, but on February 15th she complained of much pain and tenderness over the left calf, and over the front of the right thigh in the region of Scarpa's triangle. The femoral vein in the upper part of Scarpa's triangle could be felt as a firm, rather nodular, very tender, thickened cord; the limb was swollen, the tissues around the ankle were soft, and pitted on pressure. Pain was so severe that I had to give morphine, but subsequently it was much relieved by two hourly applications of belladonna fomentations.

In a week the limb had improved considerably, but the patient then complained of similar pain in the left lower limb: there was tenderness over the left femoral vein, and the calf of the leg was very swollen and tender. Swelling persisted in this leg for several days after the pain had disappeared, but massage and passive movements soon reduced the leg to its normal size.

It is interesting to endeavour to explain the actual causation of a condition of thrombo-phlebitis of the peripheral veins after pneumonia. It has been pointed out that a microscopical examination of the blood in pneumonia shows a greater density than normal of the fibrin network. Blood platelets are also greatly increased in number. Hence there is possibly an increased tendency to intravascular clotting, and since in a large proportion of all cases of pneumonia pneumococci are present in the blood, infection of clot would more readily ensue.

Reports of Societies.

THE TECHNIQUE OF BONE GRAFTING.

At a meeting of the Section of Surgery of the Royal Society of Medicine on April 5th, with Mr. CYRIL NITCH in the chair, some points in the technique of bone grafting were brought forward by Mr. C. MAX PAGE and Mr. G. PERKINS.

Mr. MAX PAGE, whose account of the work of himself and his colleague was illustrated by a large number of radiograms, said that bone grafting was now firmly established in the treatment of ununited fractures and the replacement of bone destroyed by disease or injury. It must be admitted that some parts of the life-history of bone grafts were still obscure or in dispute, and that there was considerable divergence of opinion as to the technique best adapted to secure a successful result in bone implantation. The number of bone injuries so treated during the late war, however, furnished an extensive experience, and it should be possible now to arrive at certain conclusions. He proposed to confine his remarks to cases in which he had employed a bridge graft—that is, a bone implant which filled in a definite gap in the original bone and ultimately reconstituted a part of it. He did not believe that the graft played only the humble rôle of scaffold which was assigned to it by some authors. Some portion of it at least grew and became incorporated with the host-bone. If it was assumed that the bone graft died after implantation and only acted as a scaffold, it was difficult to see why boiled beef-bone should not have the same value as autogenous, but this was not so, as he illustrated from a case in which a beef peg, even after sixteen months, showed no union with the host-bone, while an autogenous graft in a similar case became continuous with the host-bone within six weeks.

These cases (Mr. Max Page continued) confirmed the general evidence that the beef-bone peg was useless as a bridge graft, and therefore he always employed autogenous grafts. The most satisfactory source was the tibia in the greatest number of cases. The use of the fibula was favoured by some surgeons, but it might be urged against the use of this bone that its exposure and separation were not simple, and that its removal could not fail to affect the stability of the ankle. The constituents of the bone employed might be compact bone, periosteum, and cancellous bone. Compact bone was essential for strength, but it did not appear to take an active part in the formation of new bone after implantation. Periosteum had little importance in the reformation of bone in the adult, and lately he had used grafts free of periosteum. Cancellous bone seemed to be the route along which bone development occurred. The size of the graft should be two or three inches longer than the gap it was intended to bridge. The longer the graft the firmer the fixation, and with a substantial graft there was less liability to fracture and more rapid re-establishment of the full strength of the affected part. It was important that at operation the fragments should be brought into their normal alignment without tension. Both ends of the host fragments must be resected until good vascular bone was exposed. The graft must be fixed in firm contact with the host at both ends, and unless this was done success was unlikely. The method of fixation mattered little, provided the result was firm. Mechanically the most satisfactory method in his hands was intramedullary pegging at one end and what might be called an inlaid splice at the other, making a tight fit. Foreign material, such as bolts and wires, was undesirable, though necessary at times. The graft should be aseptic and planted into an aseptic field, but the presence of infection and a successful graft were not incompatible. He showed radiograms of a case which illustrated the ability of a graft to survive and thrive, despite severe infection of the surrounding tissues.

Fractures of the graft fell into two categories: (1) Early fractures, taking place within eight weeks or so after operation, while the limb was still immobilized, and there was no strain upon the bone. These fractures occurred at the junctions with the host, following non-union of one or other end of the graft, and they were really instances, not of true fracture, but of bone absorption, secondary to incomplete fixation. (2) Late fractures, occurring in cases in which the graft had been successful, with firm union at both ends. The site at which these fractures occurred was usually near the middle of the graft, and they took place owing to some strain after the limb had been released from immobilization. They

belonged to the same category as fractures of normal bone, and did not denote any shortcoming in operative technique. The prognosis of these two varieties of fracture differed widely. In the early fractures the graft definitely failed, and union never occurred. In the late or traumatic fractures union did occur, at any rate in some cases if the surgeon waited long enough.

In post operative treatment after grafting three stages were to be noted: (1) Absolute rest and immobilization for six weeks following operation in order to establish vascular continuity; (2) partial function after six weeks or so, when light use of the limb might be permitted, governed by splints; (3) complete function, when the graft had consolidated, and the strength was estimated by means of radiograms to be about half that of normal bone. The time which must elapse before full function could be permitted varied with the case and with the bone. Full function could be allowed for the radius earlier than for the tibia. The success of the graft also varied with its situation. In the humerus no special difficulties had been found, given satisfactory splint fixation. Among six bridge grafts of the humerus he had had only one failure. The radius was grafted with the greatest ease, and there had been no failures in nine consecutive cases. The ulna was less satisfactory, either because at the time of operation the fragments were not aligned without tension, or because the usual position for immobilization after grafting was incorrect. Out of seven grafts in the ulna there had been five failures. In the tibia the grafts in the upper and middle thirds gave good results; in the lower third the prognosis was doubtful. Among seven grafts of the tibia there had been three failures. Inadequate fixation of one or other end of the graft into the healthy host-bone was the factor chiefly responsible for non-success.

The CHAIRMAN asked whether, in cutting the graft, Mr. Page used an Albee saw or a hand saw. Some who were in the habit of grafting had given up the Albee saw because they believed that with heating it damaged the vitality of the bone. He also asked whether these operations had been done in one or two stages—whether the cavity and the bones had been first prepared and the wound closed, and then the graft implanted at a later date when it was quite certain that all pyogenic organisms were absent.

Mr. P. JENNER VERRALL agreed with what Mr. Page had said about mild sepsis not interfering with the result of the graft. Some two years ago, when he was using lateral grafts almost exclusively, and drilling both graft and host-bone, on two occasions in the radius he had the drilled ends come out with sequestra, and the rest of the graft united with entire satisfaction. In some of the cases of what might be called "aseptic digestion" of the graft to which Mr. Page had alluded he had found that the Wassermann reaction was positive. He did not quite agree with what Mr. Page had said about the use of the fibula. His own practice was to use it in grafting on to the humerus if by the more usual method of fixing the ends of the humerus together with a small intramedullary peg the humerus would be made ridiculously short. It so happened that the fibula almost exactly fitted inside the humerus, and he had bridged the humerus in this way in seven or eight cases, with success in all but two. One necessary caution, however, was that rather prolonged fixation was necessary with these long grafts in the humerus. The ablation of the fibula produced no ill effects on the leg whatever, nor was it difficult to perform. The great point was not to go too low down. The upper two-thirds of the fibula could be removed with complete impunity. He emphasized the value of the fibula particularly for bridging gaps where one end was free. On two occasions he had used the head of the fibula for the head of the humerus. The ulna was notoriously unsatisfactory, and he suggested that the extraordinary frequency with which ununited fractures appeared at the end of the ulna was associated with the subluxation forwards of the head of the radius. He had had several cases of the kind, which greatly complicated his methods of fixation. He thought the complete supination position kept the head of the radius in place and enabled the radius to act as a stabilizing influence. He was surprised that Mr. Page allowed any movement in the limbs as early as six weeks after grafting.

Mrs. MAX PAGE, in reply to the Chairman's questions, said that he used the Albee saw, and thought that if the saw was kept properly irrigated there was no danger of necrosis of the graft. He had had to resort very seldom to the two-stage operation; as a rule it was possible to get on with the complete operation right away. He admitted that the radio-

graphic appearance of some of the grafts was very suggestive of infection, but on the other hand there was evidence in a good many cases of a successful graft with infection above it. He and his colleague never used the fibula now for taking a graft, and therefore he could not contest the value of Mr. Verrall's methods in this respect.

TREATMENT OF UTERINE FIBROIDS.

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine on April 6th, Professor HENRY BRIGGS presiding, a discussion took place on the treatment of uterine fibroids.

Dr. W. FLETCHER SHAW, in opening, said that at the Annual Meeting of the British Medical Association in 1914 Dr. Archibald Donald stated that in a series of 399 hysterectomies which he had performed for fibroids, the mortality had been 2.9 per cent., and in view of the favourable results Dr. Donald strongly advocated operation in preference to x-ray treatment. He was followed by Professor Gauss of Freiburg, who pleaded for x rays, which he claimed gave as good results as operation; but in the succeeding discussion every British radiologist supported Dr. Donald. Since 1914 many articles had appeared in the medical press advocating the use of x rays, and therefore it seemed that the subject might well be discussed again in the light of later experience. Undoubtedly one great risk in operation was the occurrence of thrombosis followed by fatal embolism, and it was two recent disasters of this nature in the speaker's practice which caused him to set about a review of the subject. The basis for comparison must be a consecutive series of cases of uterine fibroids treated by one or other method, and a fair estimation of what the results would have been had the alternative method been adopted. During the years 1920 and 1921 he had notes of 138 patients operated on for uterine fibroids, the operation in the great majority of cases being supravaginal hysterectomy. The number of deaths was four, including two from embolism, one from shock, and one from acute nephritis. This mortality would not have occurred under radiation treatment, so that on the primary results radiation had the advantage, and, unfortunately, in literature many radiologists confined themselves to assessing primary results. But there was another side to the question. Microscopical examination was not carried out in all these cases, but among the cases in which it was carried out five cases of malignant disease were discovered. Had these five cases been treated by radiation as ordinary fibroids there was little doubt that the growth would have continued, and the ultimate death of these five patients after ineffective radiation must be set against the four post-operative deaths. Then there were twenty-two cases of marked degeneration, and it was extremely difficult to be sure without operation that a tumour was not degenerative. Adhesions between the uterus and abdominal viscera would be a contraindication to x rays, and yet it often happened that these adhesions, like degenerations, remained undiscovered until operation.

Altogether, from a study of his cases, including as they did various complications which would have rendered radiation ineffective, Dr. Fletcher Shaw could only come to the conclusion that the routine treatment of uterine fibroids by radiation was quite unjustifiable. Apparently a simple, uncomplicated, undegenerated fibroid might diminish in size and cease to bleed as a result of x-ray treatment; but how could one be certain that it was non-malignant and free from complications and degenerations? In only one group of cases was he inclined to admit that radiation might be useful: these were cases in which the haemorrhage was so severe that the patients were rendered too anaemic to stand operation without undue risk. Unfortunately, the radiologists did not seem willing to take these blanched cases.

Dr. SIMON FORSMAN said that Dr. Shaw had been more generous to the advocates of radiation than he need have been. A certain number of cases failed entirely to respond to x rays and subsequently came to operation. The great claim of the radiologists was that they avoided the risk of administering an anaesthetic, but clearly for diagnostic purposes in gynaecology such administration was necessary.

Mr. EARDLEY HOLLAND said that in 1914, in view of the advocacy of radiation in many quarters and its obvious advantage over surgery, given equally good results, he sent eight private patients to radiologists of distinction, but the results were disappointing. In two cases the fibroids were extremely small, and here the treatment was successful. In

two others the patients, after three or four courses of x-ray treatment, ultimately came to operation. Another patient, although cured of the fibroid, had a severe x-ray burn, and yet another had a burn without having been improved by the treatment. The remaining two cases he was not able to follow up, owing to the outbreak of the war.

Dr. S. J. CAMERON said that the more he studied the complications and degenerations of uterine fibroids the more convinced he was that these tumours were, if not an imminent, at least not a very remote source of danger to the individual, and he failed to see how radiation could prevent such complications and degenerations. He believed that from the point of view of risk the rival methods were about equal. Being a Glaswegian he held strongly that if silk were discarded in favour of catgut operations would be much safer. He believed that many deaths occurred from infective processes set up through the silk. With the right technique mortality from operation would be much less than mortality from x-ray failure.

Dr. A. E. GILES said that most of those who advocated the treatment of fibroids by x-rays put forward a long list of exceptions, and perhaps the list might with propriety be lengthened. If a case could be guaranteed as free from malignancy, complications, degeneration, and adhesions, it might be suitable for x-ray treatment; but there was another important consideration. Years ago, because of the risk attaching to hysterectomy, the operative treatment for fibroids consisted of removing the ovaries; but as the mortality from hysterectomy declined it began to be asked why healthy organs should be sacrificed for the sake of a diseased one. By all accounts the radiologists reckoned upon the atrophy of the ovaries by x-ray action, so that this was simply going back to the old-fashioned operation with its obvious objection. As to surgical risk, his own experience included 960 hysterectomies for fibroids, and the total number of deaths was 17; but 12 of these deaths occurred in the earlier years, among his first 300 cases, and the more recent mortality after hysterectomy in his practice was, he believed, less than 1 per cent. Myomectomy, despite obvious limitations to this procedure, had an important scope, and in many of his cases—about one out of five—the fibroid was taken away and the uterus left.

Dr. LARTHORN SMITH said that in his early years, appalled by the mortality of hysterectomy, he went over to Paris and learned Apostoli's method of treatment with continuous galvanic current. He treated more than a hundred cases in that fashion, and they did very well, and there was no mortality. But operation on the whole was more satisfactory, and with the fall in the mortality after hysterectomy he reverted to that procedure. On several occasions he had removed the fibroid during pregnancy, and the pregnancy had gone on to full term.

Dr. CLIFFORD WHITE asked what was the state of the tumour in those cases in which the unfortunate gynaecologist had to do a hysterectomy after x-rays had been unavailingly applied. If as a result of previous x-ray treatment the operation was rendered unduly dangerous on account of adhesions, the ensuing mortality should be put down to the radiologist, not to the surgeon.

The PRESIDENT supported the general opinion of the Section as to the advantages of surgery; and Dr. FLETCHER SHAW, in replying, referred to the number of degenerated tumours which had to be removed after the menopause. Frequently it was necessary to operate upon acutely degenerative tumours in oldish women, and the risk with radiation treatment of such a thing occurring after the menopause outweighed in his opinion the risk of primary mortality on operation.

Extension of Carcinoma of Cervix to Vagina.

Dr. ARCHIBALD LEITCH, at the same meeting, made a communication, illustrated by the microscope and epidiascope, on the extension of carcinoma of the cervix to the vagina. He said that from an observation of a number of cases of carcinoma of the cervix in which there were secondary deposits, and also from a study of recurrences, gynaecologists must feel that the vagina in cancer of the cervix uteri was a very dangerous zone. An analysis he had made of *post-mortem* findings in cases of carcinoma of the cervix showed that out of 847 cases there was vagina involvement in 826. Such involvement was absent in only 2.5 per cent. He did not think that this danger of vagina involvement was sufficiently met by modern operative procedures, and the

removal of a considerable portion or the whole of the vagina might be a wise precaution.

The main route by which the vagina became involved was by continuous lymphatic spread direct from the cervix. But there was another mode of possible involvement of which he wished to speak. In the older textbooks, and in some which claimed to be modern, the possibility of contact transference of cancer was put forward by three examples: from the breast to the inner surface of the arm, from one lip to the other, and from the cervix to the posterior wall of the vagina. In all these cases it was difficult to see how such transference could take place in view of the septic character of the surface of the growth, where the outer layer of cells, if not absolutely necrotic, would be devoid of any grafting vitality. In supposed transfer from breast to arm it was surprising how extensive the lymphatic dissemination was in a brawny arm; he had demonstrated on several occasions cancer cells in the lymphatics as far down as the wrist, but without any evidence of nodule formation in the skin. With regard to the lips, if the possibility of lymphatic involvement from one side to the other could be excluded, as it could not always, it might be accepted that the causal factor which induced the original growth—for example, the irritation of a clay pipe—could start a growth on the other lip, which was equally exposed. In the vagina, lymphatic spread from the cervix could often be demonstrated, but he would suggest that occasionally, apart from this, the vagina involvement might be an independent thing. The fact that vagina involvement was so rarely visible to the naked eye in early cases might be held to favour the idea that its late development was due to some prolonged operation of the same cause as produced the cervical cancer.

In making microscopic examinations Dr. Archibald Leitch said he had come across appearances in the vagina which led him to believe that independent growths might be in process of formation. It was not uncommon to observe localized hyperplasias of the vaginal epithelium, especially with keratin formation on the surface, which was certainly very abnormal. In a few cases he found, quite by accident, some advanced and suspicious changes. He did not think much about these until he began to produce cancer experimentally in mice, when the former observations assumed a new importance. In these experiments coal tar was painted on the backs of mice, and after some months little neoplasms became true infiltrating epitheliomata. The curious thing was that over the painted area these tumours only arose at certain points; there was not a uniform reaction over the exposed surface. Thus at one place there would be an epithelioma, and at another a cornifying wart, while portions of the area had escaped entirely.

The irritation theory of cancer was now assuming much importance. There was, perhaps, an undue inclination to look upon cancer as something for which an irritative cause had invariably to be found. But one naturally sought to draw a relationship between appearances found where there was a known causal agent and those found where the causal agent was not known. He showed sections of the vaginal mucosa in two cases of cancer of the cervix. In one there was evidence of deep lymphatic spread, but apart from that, and at a lower level, there was an epithelial growth of a basal-cell type, such as was found in rodent ulcer, arising in the vaginal mucosa. The other case showed a minute growth starting from the surface and penetrating irregularly into the deeper tissues. He would diagnose it as an early epithelioma; and in this case there was no deep lymphatic involvement. He suggested that this was an independent growth, due to the same cause which produced the cancer of the cervix. The same irritant, probably a diffusible one, that produced the cancer of the cervix might also produce the cancer of the vagina, quite apart from lymphatic spread.

Dr. A. E. GILES said that one other instance of apparent contact carcinoma was the presence of the disease in each labium. Here there were surfaces which exactly touched, but he would not argue that this proved transference by contact. He believed that there was a good deal to support Dr. Leitch's view. One might find carcinoma of the vagina, if not associated with, at any rate following carcinoma of the body of the uterus, where any direct extension would seem to be out of the question, and lymphatic spread a little more difficult.

Dr. FLETCHER SHAW said that a patient upon whom a hysterectomy had been done five years previously came to him with a small epithelioma in the vagina; its upper edge

was a quarter of an inch away from the original scar. It was quite irremovable, and radium was tried without result. The only explanation seemed to be a primary growth which occurred a second time in a patient susceptible to cancer. He imagined that the same primary irritation produced the second growth as produced the first.

Dr. A. LAPHORNE SMITH said that he had seen a few cases of cancer of the vagina present at the same time as cancer of the cervix, but he was astonished to hear that it was so frequent as Dr. Archibald Leitch's figures seemed to indicate. He himself had never imagined that there was any other explanation than contact.

Mr. EARDLEY HOLLAND related a case in which, after an extensive operation for carcinoma of the cervix, a completely isolated and discrete nodule of the carcinoma appeared at the extreme end of the vaginal wall, separated from the scar by two inches of healthy tissue. It might be an implantation, or perhaps due to backward lymphatic spread. In the majority of cases any recurrence after extensive abdominal operation took place, not in the vagina, but in the paravaginal cellular tissue.

Dr. CAMERON had seen several cases in which carcinomatous ulcers had been associated with, but were distinct from, a malignant growth of the cervix. He had always regarded them as being due to permeation formed by the breaking down of the cancerous nodule, but he had to fall back upon pathologists like Dr. Leitch for an authoritative interpretation. But he believed that such cases as Dr. Leitch had brought forward were rare, and that the majority of cases which spread did so by permeation, otherwise the results in radical operation would not be nearly so satisfactory as they were.

Mr. DOUGLAS DREW asked whether the explanation could be extended to cover the curious cases in which recurrences took place five or more years after the removal of the original growth. Dr. CLIFFORD WHITE instanced a case of sarcoma which involved the vagina in exactly the same way as had been stated in carcinoma. Another member had met with several cases of second primary growth in the breast, and saw no reason why, from the clinical point of view, second primaries should not occur in the vagina.

Dr. LITTLE, replying, said that the spread of sarcoma down the vagina would certainly be by lymphatic or venous routes. He believed that the great majority of recurrences in carcinoma, even when late, were by way of lymphatic spread, but in some cases such a thing as a second primary might occur. If he might speculate as to the nature of the irritant, he believed it to be diffusible, not localized, and possibly or probably a liquid, and he wondered whether it might not be traceable to some of the leucorrhoeas.

Chemical Observations on Pregnancy Toxaemias.

Dr. O. L. V. S. DE WESSELOW and Mr. J. M. WYATT read a paper on some chemical observations on the toxæmias of pregnancy, which recorded the results of a number of tests in twenty-one cases of albuminuria and six of eclampsia in the gynaecological wards of St. Thomas's Hospital, preceded by some similar observations on normal pregnancies. The chemical picture in normal pregnancy suggested an organism in a condition of comparatively low nitrogenous metabolism, owing probably to the fact that the increased demands for nitrogen were not met by a corresponding increase in protein diet among the class of people to whom the observations related. In the normal pregnant woman there was a rather low blood-urea content, slight but not very marked differences in nitrogen partition, and a very considerable increase in the fibrinogen content of the blood. In the albuminuric cases, as a whole, the blood urea was in excess of that seen in normal pregnancy, but the urea-concentration test showed a relatively lower figure. The observations directed to the functional state of the liver yielded no information of value, and it was chiefly in relation to renal function that such information was forthcoming.

Dr. HERBERT WILLIAMSON, who said that it appeared that a patient with a blood-urea content of above 0.2 per cent. must be regarded with suspicion, asked some questions of the authors, as did other members; and Dr. DE WESSELOW, in replying, said that in the normal pregnant woman one got the ordinary urea concentration found in the healthy young adult of corresponding age—between 3 and 4 per cent. He was afraid that the albumin had been neglected in these observations, but he felt that even if there was high-grade albuminuria, and the renal tests were satisfactory, it was not necessary to induce labour.

LABORATORY TESTS.

At a meeting of the Manchester Pathological Society on March 15th, with the President, Mr. J. HOWSON RAY, in the chair, Mr. HOWARTH, lecturer on biochemistry in the department of pathology, read a paper and gave a demonstration on "The newer methods of pathological investigation." He demonstrated the methods of estimating blood sugar and blood urea, and also the estimation of urinary urea, chlorides, and phosphates, making references to the clinical application of the tests and their value in different conditions. This was followed by the diastase test and those for the body alkali reserve. Mr. Howarth drew a distinction between the salt-retaining and the protein-retaining types of nephritis, and showed how they differ on estimation of blood and urinary urea and urinary salts.

Dr. G. J. LANGLEY followed with a discussion on the value to the practising physician of these laboratory tests. The speaker had found the urea-concentration tests of great value, and in cases of chronic nephritis intractable to medical measures was attempting to find in these and other urinary tests some standards which would indicate decapsulation. He referred to a case of renal glycosuria in which the blood-sugar test had enabled him to make a correct diagnosis.

Dr. OLIVER stressed the value of the various urinary tests, and commented on their use in helping to elucidate the very confused pathology of nephritis. He supported Mr. Howarth's remarks on the paramount importance of blood-sugar estimations in diabetes, and pointed out that the disappearance of sugar from the urine of diabetics did not constitute cure, as these sufferers had still a high blood-sugar figure. He had found the constant checking of the blood sugar an invaluable aid in the dieting and general treatment of diabetics.

Dr. J. B. MACALPINE restricted his remarks to the estimation of blood and urinary urea in urinary surgery. He had found the tests of the greatest possible value, and would not like to return to the old days when one operated on these cases largely in the dark as to their renal function. The chief field for these estimations lay in the ordinary prostatic enlargement. The speaker never operated upon these cases until he knew the functional condition of the kidney, and had had excellent results from this procedure. Although no test as yet will tell how much the precise anatomical damage is, he thought the blood-urea test the most valuable in general. The crude dye excretion methods, quantitatively estimated by the cystoscope, he thought fallacious.

Dr. DIBLE thought Ambard's constant a useful criterion, and believed that people were alienated from it by its formidable-looking formula. The President, in congratulating Mr. Howarth on his demonstration, called attention to the fact that Mr. Howarth would be glad to receive material for investigation from all who cared to send it to the Department of Pathology.

ROYAL ACADEMY OF MEDICINE IN IRELAND.

THE production of the *Transactions* of the Royal Academy of Medicine in Ireland has suffered serious delay by the burning of the press in Dublin which printed them.

Obstetrical Shock.

A meeting of the Obstetrical Section of the Royal Academy of Medicine was held on December 2nd, 1921, when Dr. HASTINGS TWEEEN read a paper on obstetrical shock. He said that Dale and other workers had conclusively proved that a poison generated in bruised muscle was a potent factor in obstetrical shock. Other protein material could generate this poison, and obstetricians had every opportunity of observing that it could arise in freshly effused blood. Ruptured tubal pregnancy, concealed accidental haemorrhage, and haematoma of the vulva all supplied evidence of this fact. Liquid blood was more poisonous than that which was clotted, and thus haematocoele could be accounted for. If the woman survived the initial toxic dose the blood would have time to clot. Shock was associated with a general clongation of all muscle fibres. The pupils, the anus, the bladder, the intestines, and the cheeks demonstrated this. The veins, and at a later stage the arteries, seemed to be also affected. Indeed, a great dilatation in the capillaries and veins might account for the phenomena of shock. In the uterus this clongation was better demonstrated than in any other organ, and the condition was evidently one of "retraction reversed." Contraction—a temporary shortening of muscle fibre—was under the control of the nervous system;

retraction was a property inherent to the muscle itself; it took place in a flabby, inert muscle, and was the chief factor in preventing haemorrhage. The process was slowly reversed during the growth of a pregnant uterus and rapidly reversed in shock. Accidental haemorrhage was of toxic origin; if the blood did not quickly escape its products caused shock, which led to dilatation of the uterus. The condition was therefore not due to a diseased atonic uterus, and the fallacy of hysterectomy for its relief was apparent. Caesarean section, with a smaller mortality, was more effective in the control of haemorrhage. Uterine inertia was no contraindication for delivery by forceps, for inertia was no bar to retraction. It was shock and not inertia that was to be dreaded. Lastly, the "retraction reversed" fibre was quite capable of contraction, and this was probably the condition found in the arteries during the early stages of shock.

Sir WILLIAM SMYLY said that the views propounded in Dr. Tweedy's paper would require much thought and research before one could either accept or reject them. If shock was the result of toxins in the effused blood they must develop with extraordinary rapidity and disappear almost as quickly.

Dr. SOLOMONS found difficulty in discussing the theories brought forward without more thought. While accidental haemorrhage, as suggested by Dr. Tweedy, might always be due either to toxæmia or indirect violence, he wished to know why toxæmia should be diagnosed when albumin was absent from the urine, and there were no other toxæmic signs present. He believed with some of the previous speakers that the cause of shock could not be laid at the door of any one factor; there were many such factors. He hoped that the subject would be more fully developed, and that the reason for the relief of shock by various drugs, especially morphine, would be explained.

Supports of the Uterus.

At a meeting of the Section of Obstetrics and Gynaecology of the Royal Academy of Medicine on January 20th Dr. L. CASSIDY read a paper on the supports of the uterus. He said that a careful consideration of the anatomical facts led to the conclusion that no one single structure could be regarded as of prime importance for retaining the uterus in position. Every structure which connected the uterus to the bony pelvic wall must help to fix the uterus in the pelvis, but it was only by the harmonious working of all the factors concerned that this result was obtained. The principal difficulties the uterus had to contend with were (1) intra-abdominal pressure and (2) structural injuries to the supports sustained during childbirth. With reference to the first it might be said that ordinary intra-abdominal pressure played no part at all in bringing about uterine displacement; it was only increased intra-abdominal pressure acting over a prolonged period that tended to cause this condition. The structural injuries sustained during childbirth comprised not only injuries of the pelvic floor, but also those sustained by the more important fascial structures which were present in the base of the broad ligaments.

Prognosis in Mental Disease.

A meeting of the Medical Section of the Royal Academy of Medicine was held on March 3rd, when Dr. H. R. C. RUTHERFORD read a paper on prognosis in mental disease. For purposes of comparison he made a classification of states instead of entities. He divided them into four types: depression, excitement, confusion, and delusional. An analysis had been made of 157 recoveries. A depression state was present in 63 cases. The general recovery rate, as estimated upon the admissions, had worked out at 43.13 per cent. Permanence of recovery was not to be found, as a rule, in mental disease, owing to the influence of heredity. Heredity was usually to be discerned in from 50 to 70 per cent. of admissions. This heredity he regarded as being purely of a hypothyroidal nature. He had come to this belief by the large number of patients, with an early psychopathic inheritance, who responded to thyroid treatment. Especially was this to be noticed in cases showing a family history of collateral heredity. The later hypothyroidal generations showed dementia praecox and imbecility, which conditions were accompanied by degenerative changes, or underdevelopment, and these the late administration of thyroid could not remove. He commented upon the influence of thyroid in the organism's growth, and suggested that the want of durability in degenerated tissues was due to deficient thyroid, so that when strain came the affected organ failed. Hypothyroidism only acted as a predisposing cause, but

whichever the exciting cause of the mental attack was a feeble one the administration of thyroid would remove it. There was a marked association in both the insane and their relatives of tuberculosis, asthma, and malignant disease. The author suggested that defective thyroidal secretions might act as an hereditary and predisposing cause in these diseases also.

The Treatment of Acute Infections.

Dr. W. M. CROFTON read a paper on the treatment of active immunization of acute infections, illustrated by lantern slides of the charts of patients. He discussed the theory of this method of treatment, suggesting it was always possible, so long as the endothelial cells of the blood vessels were intact. The cases described comprised acute bronchopneumonia, empyema of the knee-joint, acute thoracic infection after gunshot wounds, septicaemias following gunshot wounds of the limbs, puerperal fever, and acute pneumonic phthisis. The surgical cases had, of course, received the appropriate surgical treatment. These cases were chosen as illustrations because the patients were all quite obviously in imminent danger of losing their lives—they all had made complete recoveries.

Dr. T. P. C. KIRKPATRICK said he had seen many of the cases, and he could testify that the results were as satisfactory as had been stated. There was always difficulty in judging the relationship of cause and effect, but he felt justified in saying that the patients were distinctly benefited, and that certainly there were no harmful results. The patients themselves appreciated it. He thought that acute or advanced forms of tuberculosis did not seem to react in the same satisfactory fashion as other forms of infection.

Reviews:

ELECTROTHERAPY AND ITS APPLICATIONS.

The Principles of Electrotherapy and their Practical Application,¹ by Dr. TURRELL, Electrotherapeutic Physician to the Radcliffe Infirmary, Oxford, is, as he states in the preface, an attempt to explain the therapeutic action of electricity upon rational grounds and upon physiological principles. In its main construction it consists of four parts. The first deals with the therapeutic action of current electricity, and includes chapters upon the constant current, the interrupted currents of low frequency and of high frequency, and currents derived from the static machine. In each chapter the apparatus is described, experimental work bearing upon the subject is both quoted and illustrated, the author's own experience is largely drawn upon, and an attempt is made to work out the exact reasons why the current acts on various tissues and so brings about definite results. The chapter on the influence machine and static electricity is especially good, and contains valuable information respecting the use of the various types of machines at present available.

The second division of the book deals with the therapeutic action of radiant energy; it contains three chapters on radiant heat and light, on ultra-violet radiations, and on x rays respectively. In discussing the therapeutic action of x rays, the author takes the view that their action is simply an intensified form of the action of ultra-violet radiations, and asserts that this is in accordance with the now accepted fact that the ionization produced by x rays is due entirely to the electronic discharge or beta radiation, and not in any way to the action of scattered or secondary radiation.

In the third part, which deals with the electro-diagnosis of peripheral nerve lesions and of nervous and other diseases, the practice of allowing nurses or masseuses to take electrical reactions is strongly condemned.

In the fourth and concluding part the general lines of electrical treatment for various conditions are discussed in a series of chapters. In that on the genito-urinary system the Erlangen treatment for uterine fibroids, for sterilization, and for the cure of cancer is described, and its advantages and disadvantages contrasted. There is also in the chapter on the therapeutic action of x rays a description of the Wintz boiling-water tube, and a discussion of the reasons for the special technique. It is evident that Dr. Turrell looks upon

¹*The Principles of Electrotherapy and their Practical Application*. By W. J. Turrell, M.A., M.D., B.Ch. Oxon., D.M.R. and E. Cantab. Oxford Medical Publications. London: H. Frowde, and Hodder and Stoughton. 1922. (Demy 8vo, pp. ix + 276; 29 figures. 12s. 6d. net.)

this new method as a great advance—in fact he suggests that it is likely to revolutionize to a very large extent our views on radiotherapy; as he points out, it is largely in the direction of the attempt to place dosage on a more exact and scientific basis that the advance has been made. In discussing the dosage much stress is laid upon the lethal as opposed to the stimulating dose, and the author expresses the opinion that if 40 per cent. of the unit skin dose, as Drs. Seitz and Wintz state, has the effect of stimulating rather than destroying cancer cells, the present practice of employing prophylactic radiations before operation, and also post-operative radiation, should be immediately discontinued; this for the reason that as at present carried out in this country treatment given for these purposes does not usually exceed 40 per cent. However, the "if" with which this sentence commences is an important item in the discussion; another important point is that recurrent nodules in and around a scar after a breast has been removed for cancer are often seen to disappear completely under doses of x rays which cannot even approximate to the lethal dose of Wintz, but must be well under his 40 per cent. In this case, then, we appear to be faced with the fact that under certain conditions cancer cells are destroyed by a dose of x rays which according to Wintz is certainly not lethal but stimulating.

We have nothing but praise for Dr. Turrell's volume. It has been composed on original lines and is full of suggestive ideas. He is to be congratulated on having written a book which, whilst full of interest to every practitioner of medicine, is calculated to place electrotherapy on a more scientific basis, and to be of great assistance to all those making a speciality of this subject.

PSYCHO-ANALYSIS.

IN the preface Dr. STEKEL describes his volume, *The Depths of the Soul*,² as his favourite production. The book consists of a series of short essays or sketches dealing with a variety of topics of human interest, written at a time when the author had gained his early impressions of the psycho-analytic movement, and when, as he writes, he was experiencing "the exuberant joy of a discoverer." Though these essays reveal a knowledge of psycho-analysis, they are free from technical phrases, and might almost have been written by any wise physician of keen observation and sympathetic insight into the minds of the mentally sick and troubled. Dr. Stekel is a psycho-pathologist of repute, but these studies reveal him as an artist and poet as well. There is a subdued note of melancholy and regret in this volume which seems to reflect the mood of a physician who is sensitive to the pain of those who consult him day by day. The book makes no great demands on the reader, and may be recommended as a form of recreation to a busy doctor at the end of a hard day's work. *The Beloved Ego*,³ written by the same author, also consists of a number of sketches of different aspects of human life, and the above comments are equally applicable to this volume. The book concludes with a number of witty, and sometimes cynical, aphorisms.

The Critic and Guide Co., New York, which publishes literature concerned with sexual hygiene, has included in the series a volume by Dr. STEKEL, entitled *Twelve Essays on Sex and Psycho-analysis*.⁴ The book, it is stated, is sold only to members of the professions and to special students of sexology. The first chapter deals with sexual abstinence and health. The writer expresses his views with considerable frankness, and the tone of the essay is insufficiently restrained and dignified to render it a significant contribution towards the solution of the difficult social problem with which it deals.

We have also received four very large volumes,⁵ by Dr. STEKEL, in the original German; in them he deals at enormous length with various problems concerning sex and sexual aberrations. They may be of interest to the specialist in the subjects with which they deal.

PARASITOLOGY FOR PROBATIONERS.

Elementary Parasitology,⁶ by Mr. THOMAS T. O'FARRELL, is written for first-year nurses. It deals only with those parasites which are likely to be seen in the wards of an ordinary general hospital in Great Britain, including those which are commonly brought into the country from abroad. Attention in the first year of the nurse's training is to be focused more upon the animal than the vegetable parasites, because so many of the animals can be seen with the naked eye.

The probationers in general hospitals are hard-worked, but so much has been omitted from the book in the endeavour to shorten their studies that it has become a little difficult to understand. The choice of types for study is good, and we would not add to it; but more attention should be paid to the life-histories of the pests, both because the biology of even the most unseemly parasite is often a thing of rare beauty and interest, and also because some knowledge of the natural history is generally the only means of destroying it. One or two minor errors require correction. The ascaris is not a cousin of the earthworm, not even a distant cousin; the anopheles does not breed at the bottoms of ponds; and it is surely rather a serious omission that no reference is made to the louse as the carrier of relapsing fever. The figures are not as good as the rest of the book, and the probationer would glean little from them. We call attention to these points because we believe the conception of the book to be valuable, and that there will be a demand for its translation into certain oriental languages. If it is a little too elementary for some nurses it is just the thing for dressers and tambores, and the various types of male ward worker found in India and Egypt and China. But if it is to be used for this purpose it is essential to illustrate it with large, clear line drawings.

PROGRESSIVE LENTICULAR DEGENERATION.

DR. HALL's monograph, entitled *La Dégénérescence Hépatolenticulaire*,⁷ is a well-founded attempt to localize the cerebral degeneration underlying the signs and symptoms observed in the rare nervous disorder described by Dr. S. A. K. Wilson in 1912 under the name "progressive lenticular degeneration." As Professor PIERRE MARIE points out in his appreciative preface, neurologists tend to localize nervous disorders in the basal ganglia nowadays, just as forty years ago the localizations attempted were mainly cortical. Dr. Hall adds two further types to Wilson's original: these are Westphal and Stimpell's pseudosclerosis, and the disease described by Thomalla and by Wimmer and Neel. He provides the reader with a full discussion of sixty-eight cases in all, and at the end of his volume summarizes the conclusions to which he is led, amplifying and amending in some respects the views expressed by Wilson. The book is well written and temperately argued; it is one for the neurological specialist.

CANCER OF THE LARYNX.

THE late Mr. C. B. Lockwood used to say: "Don't read textbooks, read monographs; textbooks are made to sell." It may be hoped, however, that Dr. IRWIN MOORE's monograph on *Intrinsic Cancer of the Larynx*⁸ will "sell" as well as any textbook, for by his insistence upon the paramount importance of early diagnosis in cancer of the larynx much of what he has to say is of as great importance to the general practitioner—upon whom the duty of early diagnosis of all diseases must primarily fall—as to the laryngological surgeon. That part of the book devoted to operative technique does not, of course, concern the general practitioner or the general surgeon, for the operation is certainly not one to be undertaken lightly; but, in spite of the comparative rarity of the condition, too much stress cannot be laid upon the part devoted to diagnosis. Dr. Moore quotes a leading authority who, in referring to twenty-three cases of cancer of the larynx which he had seen, states that only one was in its early stage, which is rather a terrible commentary on the present conditions of the diagnosis of this disease. This authority suggests that "the fault lies largely

⁶ *Elementary Parasitology (First Year).* By Thomas T. O'Farrell, F.R.C.S.I., D.P.H. Dublin: Tanning and Co., Ltd., 1921. (Cr. 8vo, pp. 32; 2 illustrations. 1s. net; 1s. 6d. interleaved.)

⁷ *La Dégénérescence Hépatolenticulaire: Maladie de Wilson—Pseudosclérose.* By H. C. Hall; preface by Professor P. Marie. Paris: Masson et Cie., 1921. (Med. 8vo, pp. xi + 351. 45 figures. Fr. 20 net.)

⁸ *Intrinsic Cancer of the Larynx and the Operation of Larynxo-Fissure.* By Irwin Moore, M.B., C.M.E.D. London: University of London Press, 1921. (Roy. 8vo, pp. 159; 45 figures. 20s. net.)

with the general practitioner, who does not take sufficient notice of the early symptoms." According to the mortality returns of this country the average number of deaths from cancer of the larynx for the five years 1911-15 was 534; of every 100 deaths from cancer 1.8 are from cancer of the larynx, while 21 are from cancer of the stomach. Since the chief and characteristic symptom of the disease, in its early stage, is alteration in the voice or persistent hoarseness it is evident that a warning so definite is of infinite value in the early diagnosis of the disease, and Dr. Moore's plea for more frequent co-operation between the general practitioner and the laryngologist is completely justified.

The greater part of the book is occupied by a detailed description, fully illustrated, of the operation of laryngofissure, which has given satisfactory results in the treatment of early cases of intrinsic cancer of the larynx, both as regards life and as regards the voice. The fault of the monograph is that, while the opinions of all available authorities are quoted at every point, hardly enough stress is usually laid by the author upon his personal views. It is, however, fair to say that no throat surgeon should attempt the operation of laryngofissure without having made himself familiar with the contents of this volume, especially as the immediate success of the operation depends greatly upon the attention devoted to details which are fully set forth here. The index, it may be added, is quite unusually comprehensive and accurate.

Dr. Irwin Moore's monograph reflects credit upon British laryngology. It is evidence not only of patient and untiring industry, but of an alert and discriminating mind.

TYPICAL FLIES.

THE diptera, or two-winged flies, are of very great importance to the human race: the mosquito, the tsetse, and the flea inoculate us with the germs of fatal diseases; the fly is a major cause of all the intestinal diseases in nearly every part of the globe; other diptera adversely affect our welfare by attacking our horses and our cattle and our sheep. There is no group of insects of greater importance to us, and probably none which gives greater difficulty to anyone desirous of referring his specimens to their approximate position in classification. This difficulty is found not only by the tropical practitioner or the agricultural officer, but, to some extent at any rate, by those entomologists who have not made a special study of the diptera; an approximate identification is often a very valuable thing in tropical countries, as it frequently gives the key to the destruction of a pest without having to wait until a report is received from Europe. The principal difficulty is due to the fact that an enlarged drawing of a fly, even from the pencil of an expert, often fails to convey the same general impression as the specimen under examination; this is more true of flies than of any other group of insects. In these circumstances we extend a hearty welcome to the appearance of the second series of Mr. E. K. PEARCE'S *Typical Flies*.⁹ It is probable that his very carefully executed photographs will succeed exactly where the artist fails. It is, of course, essential that the study of these plates should be accompanied by a very careful anatomical examination of the specimen, and by reference to some work dealing with the details of classification. This is of great importance, and if care is not taken specimens will be referred to entirely wrong families because they happen to have a superficial resemblance to some insect figured in Mr. Pearce's plates. It is perhaps to be regretted that the author has not been a little more systematic in his arrangement; several quite important families of flies are not illustrated in either series—the *Calliphoridae*, for example, among others; other families are illustrated in the first series but there is no reference on the plate in the second series to the illustration of the other fly illustrated in the first series; and, lastly, there is nothing on the plates themselves to tell the student to what family the species therein illustrated refer.

Our conclusion is that we admire Mr. Pearce's photographs very much, and we believe that they serve a very useful purpose; but we should prefer to see them combined with a fuller letterpress dealing with the classification of the diptera and with an abundance of clear drawings to illustrate details of chaetotaxy and neuritation.

⁹ *Typical Flies: A Photographic Atlas*. By E. K. Pearce. Second series. Cambridge: The University Press. 1921. (Sup. roy. 8vo. pp. xiv + 33; 125 figures, 15s. net.)

NOTES ON BOOKS.

THE earlier editions of the very practical little *Experimental Physiology*,¹⁰ by Professor Sir EDWARD SHARPEY SCHAFER, have been so well known to several generations of students since the first edition appeared nearly ten years ago that it is not necessary to do more than announce the appearance of a third edition. The text has been revised, and the number of illustrations slightly increased. A certain number of the experiments described are intended for advanced students, but the selection of these is left to the teacher, since it must be regulated by the requirements of his students and the nature of the examinations for which they are working.

Dr. GIRINDRASHEKHAR BOSE, who is lecturer on physiology and abnormal psychology in the University of Calcutta, has written a small volume based upon his teachings, entitled *Concept of Repression*.¹¹ The author explains in the preface that he is "a relatively slight acquaintance with the subject, and that the views here expressed are the result of his own experience derived from clinical study during a number of years." Dr. Bose explains his concepts by the use of analogies and makes free use of analogies from the physical sciences. He relies very largely on the theory of the opposite process in explaining the process of repression.

In his lectures on *Psycho-Analysis in the Service of Education*,¹² now translated into English, Dr. OSKAR PFISTER, writing as pastor, teacher, and practising psycho-analyst, strongly urges the importance of psycho-analysis for the education of the young. As a religious instructor he places particular emphasis upon what he believes to be the moral and spiritual value of this form of treatment. He contends that teachers should themselves be analysed, and that they should receive a course of instruction in the theory and practice of psycho-analysis in order that they may be in a position to apply this procedure to the children entrusted to their care. Though Dr. Pfister writes with fervour his will probably not commend themselves to the majority of educationists, medical men, psychologists, or parents. It would seem to be most undesirable that teachers should regard it as part of their function to practise psycho-analysis upon their pupils.

The German book on headache, by Dr. LOBEDANKE,¹³ is now to be a second edition. It contains tables designed to aid in the diagnosis of the headaches respectively due to the seventeen causes the author considers most important. The pages are full of information, but appear to be of theoretical rather than practical interest.

We have received from the dental manufacturing firm of Claudius Ash, Sons, and Co., a centenary memoir commemorating the firm's hundredth year. It takes the form of a history of the firm's origin and growth entitled *A Century of Dental Art*,¹⁴ and is practically a record of the development of the art of dentistry during the last hundred years. The points in this record are of interest to the medical practitioner. A sympathetic echo is awakened on reading one hundred years ago, the dentist was dependent on the gravedigger and the body-snatcher for his supply of teeth, and a feeling almost of jealousy on learning that the first operation under ether in this country was the extraction of a lower molar! The tale of the fight for the introduction of amalgam fillings and vulcanized rubber plates evokes the most modest emotions, for the medical profession feared mere poisoning—and there was none! The memoir is well illustrated and tastefully got up. We congratulate the firm on their useful work.

¹⁴ *A Century of Dental Art*. London: Claudius Ash, Sons, and Co. 1921. (Double demy 8vo, pp. 64; illustrated.)

THE Public Health Department of the New York Academy of Medicine has published a statement that the experimental prophylactic inoculations against pneumonia carried out during the period of the war, and subsequently, have not yet yielded sufficiently convincing proof of the efficacy of the method to warrant its universal application.

THE HOSPITAL PROBLEM.

ADDRESS BY SIR JAMES GALLOWAY.

In an address to the annual meeting of the Hospital Saturday Fund, held at the Mansion House, London, on April 8th, Sir JAMES GALLOWAY, K.B.E., M.D., began by remarking that the delegates of the various committees of the association and the medical staffs of the London hospitals—their executive officers, so to speak—were partners in the enterprise of organizing our great hospitals on a voluntary system, which was one of the most noble achievements of individual and voluntary effort in this country.

A Retrospect of War Hospitals.

Sir JAMES GALLOWAY said that he had vivid recollections of the address given by him at the annual meeting of the Fund in 1915. The war had then passed its first stage, and a system of defensive warfare was being established. The country had just awakened to the great task which absorbed its full energies during the subsequent four years. The demands of war had already placed a great strain on existing medical resources, with the result that our hospital organization, both military and civilian, was in a state of rapid change and development. The military hospitals of the small regular army were expanding out of recognition to render the necessary services to our rapidly increasing armies overseas. Two main factors determined the form taken in this process of development: First, the establishment in the greater part of our fighting front of trench warfare with its peculiar character; secondly, the rapidly growing power of mobility in transport behind this stationary front. The development of transport by road, by ambulance trains, and ambulance ships became so perfect that it was possible to transport the sick and wounded from the French front to London in forty-eight hours. As the result of these conditions many hospitals immediately behind the fighting line, originally arranged as mobile hospitals and equipped for rapid movement with troops, developed as stationary hospitals, occupying the same site for years. Hospitals of this type were at that time in process of development, but it was not then known how extensive and how important these advanced hospitals were to become. These hospitals, having some security of tenure, developed equipment and facilities of medical treatment never before afforded so near the actual field of battle. They became so complete as to allow of treatment of all urgent cases under exceedingly favourable conditions, even within four or five miles of the trenches. To these hospitals were posted young and energetic medical officers. They came from all the schools of medicine in these realms and from the dominions and empire overseas, and even at the earliest stage of the war from the United States of America. These officers were confronted with new problems in the investigation and treatment of disease. Their enthusiasm and industry were so great that they made their hospitals not only of the greatest use to the army in the treatment of the sick and wounded, but centres of medical activity which influenced all those who came in contact with them. The work of every man was placed at the common disposal; the good ideas and the good plans survived. Similar conditions prevailed in the hospitals on the lines of communication and at the great base hospitals. The influence of war conditions stimulated thought and work so that these hospitals became centres of medical research from which new knowledge radiated throughout the whole medical profession.

Our hospitals at home were not slow in responding to these quickening influences. In a short time a very noticeable increase in alertness and in the practical application of medical knowledge in the treatment of disease was felt throughout the country, from our great voluntary and war hospitals to the remote cottage hospitals in the country. The profession of healing in all its branches had now more knowledge at its disposal and was more useful to the community in the application of that knowledge than at any other time, and this result was largely due to the stimulating mental influences of the Great War.

So it was also in the case of hospital organization. Large numbers of people became interested in the establishment and the equipment of hospitals during the war. Any who had the opportunity of travelling through the country during the war time, especially in its later years, must have been struck by the changed aspect of the country. On a bright

summer's day the well-known outlines of our landscapes, which gave so much pleasure to look upon, remained; the details were altered on every side by great military encampments. But one of the most interesting features, giving cause for serious thought, was the frequent appearance of the Red Cross of the General Convention. Every town, every hamlet displayed the Red Cross in some prominent position, and in many out-of-the-way corners the flag would meet the eye. In the large cities sections of the great hospitals had been given over to the use of our sailors and soldiers, while both the navy and the army had established many large war hospitals. The increase of our hospital accommodation was enormous. The amount of money expended by the nation and by private generosity seemed to know no limit. New accommodation, new equipment materialized almost when wished for. All this development greatly stimulated the interest of our people in hospital work. To the trained hospital administrator it gave unexampled opportunities of testing plans of hospital administration, of noting the points at which they failed, and of concentrating on what seemed to be the best methods. In this way, just as in the case of the medical workers, the organizers of hospitals received an intensive and excellent training during the war, and at the end of the war the country had at its disposal a larger number of persons well trained in the organization and administration of hospitals than had ever been the case before.

The After-War Reaction.

Very soon after the armistice the reaction began to appear; private generosity had long shown signs of diminishing. Many hospitals had come to depend largely, not in the old way on the gifts of individuals, but on grants from the great funds of the societies of the Red Cross and the Hospital of St. John and on payments from Government sources. These also showed signs of restriction. The demands on our great hospitals increased as the smaller hospitals closed. The peace brought the claims for hospital treatment from large numbers of sick previously under the care of various State authorities. The great epidemics of infectious disease which characterized the closing year of the war and the first year of peace strained the accommodation and financial resources of our hospitals to the utmost. No sooner had these plagues diminished than the depression in commerce and industry rapidly developed with great increase in the cost of all commodities. The necessary expenditure of hospitals doubled and more than doubled in the years following 1918. For all these reasons the hospitals of the country were now passing through the most serious financial strain ever known; some even had to close their doors; others were just beginning to revive from the strain they had passed through.

The contrast therefore was striking. At a period when their medical efficiency was at its highest and their administration by both lay and medical workers most effective, the institutions themselves had been brought within sight of ruin. But to the audience Sir James Galloway addressed he was sure that the response could only come in one sense—namely, that notwithstanding the present difficult and even perilous position of our hospitals, the voluntary system of support must go on intact and undiminished.

The Changing Hospital Clientèle.

Another aspect of the position of our voluntary hospitals arose from the circumstance that these hospitals were now giving free service to a much larger proportion and to very different classes of the population than they had been accustomed to do in the past. This great change was due to the fact that appropriate and adequate medical treatment was more difficult to obtain and its cost had greatly increased. Until comparatively recently a doctor was able to arrange for and to give the necessary treatment to the majority of those who consulted him. In some cases he required assistance, while in others the special opinion of a trained consultant or the operative skill of a practised surgeon was necessary; but with such exceptions the doctor in charge would proceed to carry out treatment on his own responsibility. Owing to the rapid advance of medical research and knowledge greatly stimulated by the war, this was no longer the case. Often the doctor in charge was unable to form a satisfactory opinion as to the exact nature of the malady or to arrange for appropriate treatment without a considerable amount of preliminary investigation. Such investigation required special skill and much practice to render it of real service. The doctor in charge usually had neither the

time nor the equipment to carry out these investigations. They might require a special knowledge of chemical and physical science beyond the ordinary medical experience. Such investigations were now carried out by medical men with special training and skill. When this information had been obtained and collated the doctor in charge was in a position to form an opinion of much greater value to his patient and to arrange for the most effective treatment. In other cases the help of a skilled operator might become necessary. Thus the work of several doctors was often needed before the most suitable treatment was determined and could be carried out. The system of combined work not only increased the financial cost but required careful proper medical treatment to large numbers of persons, even to those in comfortable circumstances, was so great as to be almost prohibitive. In the ease of medical treatment involving the cure of sickness and the lives of the people this must not be permitted: the sick must have the full advantage of the best medical knowledge. The hospitals had this knowledge and medical experience in their gift. In the process of years of growth a system had developed whereby both the personal skill and the co-ordinated efforts of their medical officers were available in the most expeditious manner; these facilities were at the immediate disposal of the poorest and most needy in the land. Were those in better circumstances to be precluded from these benefits? Obviously this could not be. Hence the hospitals were no longer a haven for the greater poor alone, but were resorted to by many others with greater financial resources. It seemed therefore that our voluntary hospitals must make arrangements for serving at least three classes: First, the necessitous poor, not provided for by the State, and for whom adequate treatment could only be obtained at the voluntary hospitals. Secondly, the workers both by hand and brain who received an income sufficient for the needs of themselves and their families, but who had neither the facilities nor a sufficient financial margin to provide adequate medical treatment at home. Thirdly, those who might have a margin above that required for their daily necessities, but when faced with severe or difficult illness could not afford adequate medical treatment. And there might find that the only place where the appropriate and satisfactory treatment available was in a well-equipped modern hospital. All these persons could not be precluded from treatment; they must have the opportunity of securing restoration to health and of preserving their lives. The voluntary hospitals were therefore coming more and more into a position in which they must be prepared to serve persons drawn from many sections of the population, and the financial responsibility of these institutions was not likely to diminish.

Paying Patients.

One of the difficulties arising under these new conditions was that persons now admitted into general hospitals were able to pay in part or in whole for their maintenance, while others could pay the full cost of maintenance and also of treatment. Arrangements were urgently required to deal with this situation. To provide accommodation for paying patients seemed to be not only an urgent need but a desirable reform in the organization of hospitals. A method whereby hospitals, besides receiving those unable to pay, also arranged accommodation for patients able to pay part or the whole of their maintenance and the cost of their treatment, had been found useful and successful in many places throughout the empire and elsewhere. It appeared as though this change were in process of development at home also.

Such changes involved a reconsideration of the position occupied by the voluntary workers. In the case of those not only willing but anxious to pay the voluntary services hitherto given should clearly not be accepted. Financial readjustments would no doubt affect the medical services, the nursing services, and other services now afforded to the hospitals on a voluntary basis. These adjustments and rearrangements should not prove impossible nor unduly difficult if the underlying principles of voluntary organization and administration were insisted on and maintained. But when all this was done the outstanding feature of our voluntary hospitals would remain—namely, that the main reason for their existence was their services rendered as a gift to the sick who could not afford adequate medical

treatment; the sick and injured would still receive the best care and treatment possible by the good offices of their fellow citizens who would continue to lay aside from their hours of work, or from their earnings, or from their worldly goods, the assistance freely given to these voluntary institutions. Were this thoroughly understood, Sir James Galloway believed there was no fear that the generosity of our people would fail to support the hospitals.

The Voluntary Hospital Spirit.

It was important that the social customs of the voluntary hospitals should be emphasized. This atmosphere of comfort and friendliness was brought about not only by the work of the medical and nursing staffs, who in such hospitals must regard their patients as individuals rather than collections of sick folk, but also by the various activities of other voluntary workers. Friends from outside the hospital, guilds of lady helpers, others dealing with convalescent patients and after-care, played an important part; indeed the activities of these might be taken in some respects as an index of the general efficiency of a voluntary hospital. They helped to distinguish our voluntary hospitals from most of the general supported hospitals, such as the infirmaries of the State, the municipal hospitals, or even hospitals under military administration.

The hospital was a large undertaking; to manage it efficiently requires business training and business ability. These requisites could be provided to a large extent by the hospital secretaries—an invaluable corps of national workers. But the best results in hospital administration were obtained by the continuous work of voluntary administrators, accustomed to the efficient management of large undertakings, associated with a capable executive—the secretary and his staff. Every means should be taken to encourage the non-medical workers, such as men in professions and in commerce, manufacturers, those accustomed to financial administration, and others dealing with the trade and work of the locality in which the hospital was situated. Those who were fit to do so should be invited to devote a part of their time to hospital administration. Much was heard at the present time of the dangers besetting the voluntary hospital system, such as the failure of funds, and their enlargement to admit contributing and paying patients. These difficulties were not so great as appeared, and they could be surmounted. The real danger which beset our hospitals was the risk of failure in attracting men with experience of affairs, in finance, and in the administration of large enterprises.

The amount of added financial assistance required was, after all, not very great; a comparatively small amount of help from all would relieve the urgent necessities of our hospitals and promote their efficiency. To conform to the voluntary system these gifts from all classes must be free and without restrictions. The whole spirit of voluntary support disappeared when the question of bargaining entered into the donation. If efforts were made that the donors might have preference or acquire special privileges, the essence of the free gift went, and the grace of the gift was lost. If the givers attempted to make bargains, the voluntary workers must necessarily do so. The dangers now arising in this way were very considerable. Some hospitals, on account of financial stringency, had recognized that many of those who sought their help were able to pay, at least to some extent, if asked for payment while under treatment. The urgency of the occasion might perhaps be held to excuse this departure from older practice. In some cases these gifts had gone far to make up the financial deficiency and to balance the hospital accounts; but it was a matter of common knowledge that difficulties had arisen. Some of those who paid, even in small amounts, thought they should receive preference above those who did not pay; while the very fact of payment brought to the surface the difficult underlying problem—namely, at what point in the case of those who paid could voluntary service no longer be offered. It could not be too strongly insisted upon that donations to voluntary hospitals, whether as personal gifts or in the form of massed contributions from groups of individuals, must still be free gifts in the full sense of the word. Any attempt to drive the hospitals into a position in which they underlook responsibility of the nature of insurance against illness for those who contributed would, in Sir James Galloway's opinion, not only be a disastrous financial undertaking on the part of the hospitals, but would bring about such a change in administration as to alter completely the voluntary system.
